Surveillance for variant CJD: should more children with neurodegenerative diseases have autopsies?

ABSTRACT

Objectives To report investigations performed in children with progressive neurodegenerative diseases reported to this UK study.

Design Since 1997 paediatric surveillance for variant Creutzfeldt-Jakob disease (vCJD) has been performed by identifying children aged less than 16 years with progressive intellectual and neurological deterioration (PIND) and searching for vCJD among them.

Setting The PIND Study obtains case details from paediatricians who notify via the British Paediatric Surveillance Unit.

Participants Between May 1997 and October 2017, a total of 2050 cases meeting PIND criteria had been notified and investigated.

Results Six children had vCJD. 1819 children had other diagnoses, made in 12 cases by antemortem brain biopsy and in 15 by postmortem investigations. 225 children were undiagnosed: only 3 had antemortem brain biopsies and only 14 of the 108 who died were known to have had autopsies; postmortem neuropathological studies were carried out in just 10% (11108) and only two had prion protein staining of brain tissue. Of the undiagnosed cases 43% were known to come from Asian British families.

Conclusions Most of the notified children had a diagnosis other than vCJD to explain their neurological deterioration. None of the undiagnosed cases had the clinical phenotype of vCJD but brain tissue was rarely studied to exclude vCJD. Clinical surveillance via the PIND Study remains the only practical means of searching for vCJD in UK children.

INTRODUCTION

The first cases of variant Creutzfeldt-Jakob disease (vCJD) in young adults were reported by the National Creutzfeldt-Jakob Disease Research and Surveillance Unit (NCJDRSU) in 1996. Until 2016, all the 177 definite and probable cases of vCJD had occurred in patients who were methionine homozygous (MM) at codon 129 of the prion protein gene (PRNP). However, in January 2017, it was reported that vCJD had been confirmed in a man who was methionine/valine (MV) heterozygous at PRNP codon 129. In the general population of the UK about 44% have the MM genotype and 45% are MV, which raises the possibility of a second wave of vCJD cases in those with the MV genotype. In addition, there are concerns about surgical and bloodborne transmission, so there is a need for continuing national surveillance for vCJD.

When vCJD was reported in adults it raised the possibility that it might occur in children and it was therefore necessary to search systematically for cases of vCJD among the many neurodegenerative disorders of childhood. In 1997, the PIND Study commenced via the British Paediatric Surveillance Unit (BPSU). Paediatricians in the UK are asked to notify all patients aged less than 16 years with “progressive intellectual and neurological deterioration” (PIND) because this group of children is likely to include any cases of vCJD.

Most of the children notified to the PIND Study have an underlying diagnosis other than vCJD to explain their deterioration. However, vCJD could be hidden among undiagnosed cases. This paper considers the public health issues raised by this undiagnosed group, including an analysis of any differences according to patient ethnicity as there...
The BPSU has studied rare childhood disorders since 1986. All UK consultant paediatricians are requested to notify children with conditions under surveillance using a monthly online system. Currently 3580 paediatricians are involved and over 2050 notifications of all children meeting the case definition for PIND shown in box 1 (see the protocol in the BPSU section of the Royal College of Paediatrics and Child Health website).

Clinical information is obtained via a questionnaire completed by the notifying paediatrician, via telephone interview or by site visit; there is no contact with the patients or their families. The study records information about presenting symptoms and signs and follows progress after presentation.

Classification of ethnicity is that used by the then Communicable Disease Surveillance Centre, Colindale, London, UK, when the PIND Study commenced in 1997. The categories are: White, Black, Indian, Pakistani, Bangladeshi, Chinese and Other. Some clinicians reported that their patients were ‘Asian unspecified’. For the current analysis the categories Indian, Pakistani, Bangladeshi, Chinese and ‘Asian unspecified’ were combined under the definition for PIND shown in box 1 (see the protocol in the BPSU section of the Royal College of Paediatrics and Child Health website).

RESULTS

Between May 1997 and October 2017, a total of 4244 children had been notified to the PIND Study. Of these, 1933 were found not to meet the PIND criteria and 261 were either still under investigation or clinical details were pending. The other 2050 cases met the PIND criteria and had been fully investigated; 6 had vCJD (identified between 1997 and 2000) and 1819 (89% of the PIND cases) had a diagnosis other than vCJD to explain their deterioration. In the remaining 225 children (11% of the PIND cases) investigations had been negative or they had died undiagnosed.

The 1819 diagnosed cases

In the diagnosed group 977 were male, 842 were female; the ethnic distribution is shown in figure 1. The proportion of Asian British families in the diagnosed group was 29% (483/1683 for whom ethnicity was known). The rate of consanguinity in the diagnosed group was 32% (461/1440 for whom consanguinity was known). The 483 Asian British children comprised: 327 Pakistani, 43 Indian, 43 Bangladeshi, 5 Chinese and 65 Asian unspecified. The rate of consanguinity in the families of Pakistani origin was 85% (279/327). In the whole diagnosed group there were more than 190 different disorders; figure 2 shows the 10 disorders identified most frequently.

In 13 cases a brain biopsy had been performed during life and 12 helped to make the diagnosis. Of the diagnosed children 241 were reported to have died; information about postmortem examinations was available for 109. Twenty-four of 109 (22%) had postmortem examinations of whom 20 had postmortem neuropathology (17 full autopsies, 1 coroner’s case without neuropathology, 3 limited to brain and spinal cord pathology, 1 limited to biopsies of skin, muscle and liver, 1 liver biopsy only and 1 muscle biopsy only). Of the 24 postmortem studies 15 helped to make the diagnosis and nine did not. Thus, the diagnosis was made without information from brain biopsies or postmortem examinations in 1819 – (12+15)=1792 cases (99%). The percentages known to have had postmortem by ethnic group were: White 21/1104=2%, Pakistani 2/327=1%...
and Indian 1/43=2%. The last reported diagnostic postmortem was in 2007.

The 225 undiagnosed cases
In the undiagnosed group 118 were male, 107 were female; the ethnic distribution is shown in figure 1. There was a high rate of consanguinity—52% of those for whom the data were available (100/194). The proportion of Asian British families in the undiagnosed group was 43% (94 of 217 for whom ethnicity was known). The 94 Asian British children comprised: 72 Pakistani, 7 Indian, 4 Bangladeshi and 11 Asian unspecified. The rate of consanguinity in the families of Pakistani origin was 89% (64/72), compared with 7% (8/108) in the White families.

The 225 undiagnosed cases had usually been very thoroughly investigated with, where appropriate, metabolic tests, neurophysiological studies, brain scans, karyotyping, DNA studies, skin, muscle and rectal biopsies as shown in table 1.

CT brain scans were performed in 65/223 (29%) (2: information not available) and at least one MRI brain scan was performed in 184/224 (82%) (1: information not available).

Table 1 Specialised investigations reported in the 225 undiagnosed cases during life, in addition to extensive biochemical studies of blood and urine

| Investigation                                      | Cases (n) |
|----------------------------------------------------|-----------|
| MRI brain scans                                    | 184       |
| Electroencephalogram                               | 159       |
| Cerebrospinal fluid examination                    | 115 (85 for lactate level) |
| White cell lysosomal enzyme study                  | 89        |
| Electoretinogram/visual evoked potentials          | 74        |
| CT brain scans                                     | 65        |
| DNA studies for known mutations                    | 49 (23 of these for known mitochondrial disorders) |
| Muscle biopsy                                      | 46        |
| Skin biopsy (often for culture of skin fibroblasts) | 31        |
| Nerve conduction study/electromyography            | 27        |
| Chromosomes                                        | 18        |
| Bone marrow for histology                          | 6         |
| Rectal biopsy                                      | 5         |
| Brain biopsy                                       | 3         |
| Conjunctival biopsy                                | 2         |
| Liver biopsy                                       | 1         |

Table 2 Principal abnormalities reported on CT and MRI brain scans in the 225 undiagnosed cases

| Principal abnormality                              | CT brain scans | MRI brain scans |
|----------------------------------------------------|----------------|----------------|
| Normal                                             | 28             | 45             |
| Cerebral atrophy                                   | 20             | 33             |
| Cerebellar atrophy                                 | 1              | 9              |
| Generalised atrophy                                | 3              | 32             |
| White matter abnormalities                          | –              | 25             |
| Basal ganglia changes                              | 5              | 8              |
| Intracranial calcification                         | 5              | –              |
| Periventricular low intensity                       | 1              | –              |
| Mixed (atrophy plus white matter abnormalities)     | –              | 24             |
| Other*                                             | –              | 7              |
| No result                                          | 2              | 1              |
| Total                                              | 65             | 184            |

Forty-nine children had both CT and MRI scans, so there was overlap in the findings on the scans. Brainstem abnormalities reported on MRI scans: small/atrophy 6, signal abnormalities 2. None of these findings were reported as the principal abnormality on the relevant scan so these cases are included in the numbers shown in the table.

*Partial callosal agenesis, microcephaly, ventriculomegaly, hypoplastic optic chiasm, right hemiatrophy, multiple small infarcts, arteriovenous malformation.
The principal abnormalities found on these scans were heterogeneous (see table 2).

It was reassuring that none of the MRI scans were reported to have the pulvinar sign associated with vCJD. MRI brain scans were performed in 73/94 (78%) of the Asian British children compared with 92/108 (85%) of the White children, suggesting that Asian British children were being as thoroughly investigated as White children because MRI scans are not easily performed in this age group.

In three undiagnosed children a brain biopsy had been performed during life. In 123 cases the child’s death had been reported. Postmortem pathological examinations had been carried out in 14 (13%) of the 108 cases for whom information was available: 9 had a full autopsy and 5 had partial examinations (in 1 the brain was not examined, in 2 just the brain was examined, in 1 postmortem liver and muscle biopsies were taken and 1 had a postmortem liver biopsy). Postmortem neuropathological examination was carried out in 11 cases, in two of these brain tissue was sent to the NCJDRSU where staining for abnormal prion protein was negative. In another case, the neuropathology was reviewed by the NCJDRSU and was not that of vCJD. In the ethnic groups the percentages that had postmortems were: White 8/108 = 7%, Pakistani 4/72 = 6% and Indian 2/27 = 29%.

Children were not routinely followed by the Study after being allocated to the undiagnosed group. Therefore, in October 2017, the National Health Service Spine Portal was used to discover how many of the 225 undiagnosed cases had died by that time: the total number was 161, which is 38 cases more than had been reported by the notifying paediatricians between May 1997 and October 2017.

DISCUSSION
Principal findings
Postmortems and diagnosis
The diagnosis was made without brain biopsy or postmortem neuropathology in 99% of the whole diagnosed group of children with PIND. Only 24 children in the diagnosed group were known to have had postmortem examinations. However, these did help to make the diagnosis in 15 cases. It is therefore a concern that only 14 of the 108 undiagnosed children who died were known to have had postmortem studies and in three of these the brain was not examined.

Falling autopsy rates have been noted in adults and children. Burton and Underwood reported that the overall autopsy rate in the UK in 1979 was 42.7%, falling to 15.3% in 2001. In 2015, Turnbull et al. found that the mean autopsy rate in the UK was 0.69%: hospital autopsy rates in children’s hospital NHS trusts ranged from 0% to 21%. A recent systematic review of postmortem examinations in perinatal and paediatric settings stated, ‘…PM examinations result in clinically significant findings in 22%–76% of cases.’

Possible hidden vCJD
It is reassuring that the majority of notified UK children who met the PIND criteria had a diagnosis other than vCJD to explain their deterioration. However, 225 of them had no diagnosis—could some of them have vCJD? A previous short report by the PIND Study provided reassurance about this and the current data reinforce the view that there is no evidence of hidden vCJD in undiagnosed children with PIND; none fulfilled the sensitive and specific diagnostic criteria for ‘probable’ vCJD (see table 3).

However, it is a concern that prion protein staining of brain tissue was carried out in just two of the undiagnosed cases as this is the only way to completely exclude the diagnosis of vCJD. Blood and urine tests for diagnosing vCJD have been developed, but are not sufficiently validated for routine clinical use.

Ethnicity and consanguinity
The PIND Study has reported that the greatest numbers of cases come from areas where there are relatively large populations of Pakistani origin. These new data confirm that a large proportion of Study children are Asian British (29%) in the diagnosed group and 43% in the undiagnosed group compared with 7.5% in the general population of England and Wales in 2011. There were high rates of consanguinity—in the families of undiagnosed children of Pakistani origin with PIND it was 89%; possibly they have inherited neurodegenerative diseases that have not yet been characterised. These diseases may become evident as new diagnostic investigations are available.

Strengths and weaknesses of the PIND Study
The Study uses the well-established health surveillance mechanism of the BPSU. The PIND Study Expert Group includes representatives from the NCJDRSU and provides an independent opinion about the diagnosis in every reported case. There is multisource ascertainment and the reporting is not restricted to cases admitted to hospital. The Study has confirmed the diagnosis of more than 190 known neurological disorders and has published case series of the diagnosed groups.

Table 3 Current diagnostic criteria for vCJD as reported by Heath et al. in 2010

| Subsection | Item | Criterion |
|------------|------|-----------|
| I A | Progressive neuropsychiatric disorder |
| I B | Duration of illness >6 months |
| I C | Routine investigations do not suggest an alternative diagnosis |
| I D | No history of potential iatrogenic exposure |
| I E | No evidence of a familial form of TSE |
| II A | Early psychiatric features* |
| II B | Persistent painful sensory symptoms? |
| II C | Ataxia |
| II D | Myoclonus or chorea or dystonia |
| II E | Dementia |
| III A | EEG does not show the typical appearance of sporadic CJD† in the early stages of illness |
| III B | Bilateral pulvinar high signal on MRI scan |
| IV A | Positive tensin biopsy§ |

*Depression, anxiety, apathy, withdrawal, delusions.
†This includes frank pain and/or dysesthesia.
‡The typical appearance of the EEG in sporadic CJD consists of generalised triphasic periodic complexes at approximately 1%. These may be occasionally seen in the late stages of vCJD.
§Tensin biopsy is not recommended routinely, nor in cases with EEG appearances typical of sporadic CJD, but may be useful in suspect cases in which the clinical features are compatible with vCJD and MRI does not show bilateral pulvinar high signal.
¶Spongiform change and extensive prion protein deposition with florid plaques throughout the cerebral and cerebellum.
EEG, electroencephalography; TSE, transmissible spongiform encephalopathy; vCJD, variant Creutzfeldt-Jakob disease.
The BPDSU relies on the voluntary support of consultant paediatricians: it does not provide complete ascertainment of cases and it is not always possible to obtain all the relevant data. When PIND cases are diagnosed they are not systematically followed up by the Study and follow-up has to be discontinued eventually in undiagnosed cases.

UK surveillance for prion diseases is carried out by the NCJDRSU, the team that first identified this new disease. The NCJDRSU relies on a network of neurologists, psychiatrists, neuropathologists and other clinical specialists who report adults with suspected vCJD. Because vCJD cases could be hidden among the multitude of rare neurodegenerative diseases of childhood a system of direct referral of suspected vCJD cases would not be reliable. The PIND Study therefore has to work via local paediatricians and other specialists to screen all the children in the UK with PIND.

Policy implications and future research

There has been increasing use of minimally invasive postmortem investigations in infants and children. Postmortem MRI can provide useful diagnostic information and may identify significant neuropathology in infants and children. Storage of blood and other relevant tissues for metabolic and/or genetic studies is very important; several PIND Study children have been diagnosed via the UK and Ireland Deciphering Developmental Disorders Study. Some children with undiagnosed PIND might be eligible for inclusion in the 100 000 Genomes Project. Because of the recent advances in genetics undiagnosed children should be referred for an up-to-date opinion from a clinical geneticist.

The recent identification of the first patient with vCJD who was MV heterozygous at PRNP codon 129 reinforces the need for continued vCJD surveillance, particularly as a study of the National Creutzfeldt-Jakob Disease Research and Surveillance Unit, Western General Hospital, Edinburgh, UK.
