Pulmonary vein stenosis: Case report and literature review

R Amin MD, S Kwon BSc, Y Moayedi BHsc, N Sweezey MD

BACKGROUND: Pulmonary vein stenosis is a rare cause of pulmonary hypertension, with variable onset and presentation. One or more of the four pulmonary veins can be primarily or secondarily affected. A five-month-old girl presented with respiratory distress, lethargy and cyanosis requiring intubation.

METHODS: Echocardiography showed right ventricular dilation, a right ventricular systolic pressure of 97 mmHg, decreased ejection fraction and turbulent flow at the left atrium. Cardiac catheterization revealed stenosis of the left-sided pulmonary veins, for which she underwent a Coles procedure.

RESULTS: Postoperatively, there was a transient improvement in the patient’s pulmonary hypertension but she subsequently deteriorated. Her prognosis was considered bleak, and a decision was made with the family to withdraw care.

CONCLUSION: Pulmonary vein stenosis is a rare cause of pulmonary hypertension, and is associated with significant morbidity and mortality. Surgical intervention may be of benefit in selected cases. It stands to reason that any treatment will have the best chance of success if completed before the pulmonary hypertension becomes fixed. Early diagnosis depends on a high index of clinical suspicion.

Key Words: Coles procedure; Pulmonary hypertension; Pulmonary vein stenosis

CASE PRESENTATION

A five-month-old girl presented with a history of cyanosis, lethargy and an oxygen requirement of 1 L/min by nasal prongs.

Following birth at 25 weeks gestational age, the patient developed respiratory distress syndrome and, subsequently, bronchopulmonary dysplasia (BPD). She underwent high-frequency oscillation for 11 days, was conventionally ventilated for 73 days and finally, extubated after a 48 h course of dexamethasone. Her neonatal course was complicated by decreased right vocal cord movement, tracheomalacia, patent ductus arteriosus, and ligation and pulmonary hypertension, for which she received sildenafil. She also had a gastrostomy tube placed because of gastroesophageal reflux and aspiration. She was discharged on 200 mL/min of oxygen. On presentation to the emergency room at the Hospital for Sick Children (Toronto, Ontario), her medications comprised sildenafil, hydrochlorothiazide, spironolactone, sodium chloride supplements, budesonide, domperidone, lansoprazole, iron and multivitamin supplements (Trivisol, Mead Johnson, Canada).

The patient was afebrile, with a respiratory rate of 70 breaths/min, oxygen saturation at 94% on 60% oxygen in a head box and a systolic blood pressure of 70 mmHg. She had stridor, moderate to severe indrawing and no digital clubbing. There was a right ventricular heave, a single, loud S2 and a grade 2/6 systolic murmur heard throughout the precordium. Her liver was palpable 3 cm below the right costal margin. The remainder of the physical examination was unremarkable.

The patient’s venous blood pH was 7.34, with partial pressure of carbon dioxide at 53 mmHg and a white blood cell count of 15×10^9/L. A chest radiograph revealed cardiomegaly with a large right atrium, prominent pulmonary vessels and bilateral interstitial thickening. Echocardiography ascertained a right ventricular systolic pressure of 97 mmHg, with a concurrent systolic blood pressure of 70 mmHg measured in the right arm. There was moderate tricuspid regurgitation and a dilated right ventricle, with a severely reduced ejection fraction (Figure 1). The interventricular septum was bowed toward the left ventricle in systole and was flat in diastole. Turbulent flow at the orifice of the left atrium was also seen, suggestive of stenosis of the left lower pulmonary veins.

The patient was transferred to the intensive care unit, where bilevel positive airway pressure was initiated. Sildenafil was continued, nitric oxide at 20 parts per million was started...
and she was diuresed. After blood and nasopharyngeal swab cultures were obtained, she was started on antibiotics empirically. However, she deteriorated 48 h later and was intubated because of poor oxygenation. She developed hemodynamic instability, which was managed with intravenous epinephrine, milrinone and dopamine.

A computed tomography (CT) scan of the chest showed enlargement of the right ventricle and main pulmonary artery, diffuse reticular markings of the lung parenchyma and a hypoplastic left pulmonary artery (Figure 2). Cardiac catheterization confirmed severe stenosis of the left-sided pulmonary veins at the junction of the left atrium, normal right pulmonary veins and an elevated pulmonary vascular resistance of 17 Wood units.

Open surgical repair in the form of a left-sided Coles procedure was performed. An intraoperative transesophageal echocardiogram demonstrated a right ventricular systolic pressure of 52 mmHg (systolic blood pressure of 89 mmHg measured concurrently in the right arm). The patient failed multiple attempts at extubation. She redeveloped suprasystemic pulmonary hypertension and was treated with sedation, muscle paralysis, nitric oxide, sildenafil, prostacyclin and diuresis. Despite this management, she developed worsening cardiac function with increasing compromise of the left ventricle. She failed to improve and a decision was made with the family to withdraw care.

DISCUSSION

Pulmonary vein stenosis (PVS) is a rare condition, with a reported prevalence of 1.7 per 100,000 children younger than two years of age (1). It is exceptionally difficult to manage, and is associated with less than a 50% survival rate within five years of diagnosis (1,2). PVS has been reported in 0.5% of pediatric autopsy cases (3).

Historically, PVS has been considered to be a congenital abnormality, but primary PVS is the preferred terminology because the literature suggests that PVS is progressive and may not be present from birth (2). Primary PVS is believed to result from the abnormal incorporation of the common pulmonary vein into the left atrium in the later stages of cardiac development (4). However, recent evidence (2) suggests that PVS can also be secondary, and may develop as a result of cardiopulmonary surgery or catheter intervention. Approximately one-half of pediatric patients with primary PVS have an associated cardiac defect (2). Similar to the present case, primary PVS has also been associated with BPD and preterm birth (2,4). It has been hypothesized that many of the factors that predispose patients to BPD may, in fact, also contribute to the development of PVS in the preterm infant (1). In pediatrics, secondary PVS occurs most commonly after surgical treatment for total anomalous pulmonary venous drainage (2). Clinically significant PVS occurs in 10% of postoperative total anomalous pulmonary venous drainage patients (5,6).

The pathophysiology of PVS is helpful in understanding the clinical presentation. There is a diverse spectrum of disease. The stenosis usually occurs at the anastomosis between the left atrium and the pulmonary vein confluence, or may extend into the individual pulmonary veins (1). A left-sided PVS causes increased back pressure proximal to the stenosis, decreasing left pulmonary artery flow and increasing right pulmonary artery flow. Ventilation and perfusion mismatch results, with decreased gas exchange in the left lung (7). Over time, the left pulmonary artery becomes hypoplastic because of longstanding decreased blood flow. As a result, these patients are more sensitive to pulmonary stresses such as infection.

Our patient had unilateral PVS but with radiographic evidence of bilateral reticular markings consistent with pulmonary edema. As a consequence of left-sided PVS, hydrostatic pressure was elevated secondary to pulmonary venous hypertension and left-sided pulmonary edema developed as per Starling’s forces. However, bilateral pulmonary edema explained the patient’s acute deterioration. The pulmonary hypertension crisis at the time of presentation led to hypoxemia that triggered an increase in pulmonary vascular resistance, increased hydrostatic pressure and worsened pulmonary edema. Given the extent of the baseline pulmonary hypertension in our patient, pulmonary vascular recruitment was likely limited, which explained the inability of the pulmonary circulation to accommodate an acute increase in pulmonary pressures. The latter, in combination with the underlying BPD, may account for the patient’s cardiorespiratory failure despite unilateral disease.

PVS typically presents in the first few years of life. There is debate as to whether the number of pulmonary veins involved and the degree of obstruction affects the onset and severity of presentation (2,8). Symptoms of pulmonary hypertension are not typical at early presentation – patients often present with tachypnea and recurrent pneumonia instead (2). As the disease progresses and pulmonary hypertension becomes more prominent, patients may develop a new murmur, right ventricular heart failure and pulmonary edema, failure to thrive or hemoptysis (1,2,7).

Noninvasive tests such as echocardiography with Doppler ultrasound, magnetic resonance imaging, multidetector CT angiography and radionuclide quantitative pulmonary flow imaging may detect PVS (2,9). The finding of turbulent flow on echocardiography with Doppler ultrasound should raise the suspicion of PVS (2). Because patients with PVS often have cardiac anomalies, pulmonary hypertension may mistakenly be attributed to the cardiac findings instead of the underlying pathology.

Figure 1) Echocardiogram showing a dilated right ventricle compressing the left ventricle and a bowed interventricular septum.
PVS (2,9). In addition to the right ventricular failure in the present case, our patient also had mild BPD that was out of proportion to the degree of pulmonary hypertension. Visualization of all four pulmonary veins in patients with unexplained pulmonary hypertension or cardiac abnormalities on echocardiography is recommended. Magnetic resonance imaging and CT angiography are also useful noninvasive diagnostic tools for PVS. Both are able to provide three-dimensional views of the pulmonary veins but are limited by spatial resolution (2).

Given the ventilation-perfusion mismatch that develops in the context of one-sided PVS, radionuclide quantitative pulmonary flow imaging is an excellent tool to evaluate the distribution of pulmonary blood flow. This tool is useful to evaluate patients preoperatively and to follow them over time (2).

There are reports of missing PVS when using noninvasive diagnostic techniques alone (1). Therefore, cardiac catheterization (or angiography) remains the gold standard for the diagnosis of PVS. A catheter is advanced into the pulmonary arteries, and segments that drain each of the pulmonary veins are identified; if PVS is present, flow will be reduced or absent (2).

The management of PVS is surgical and, presently, the Coles procedure (a 'sutureless' technique) is the preferred surgical repair method (1,2,10). An incision is made in the left atrium and along the entire length of the pulmonary vein confluence, which can be continued into the individual pulmonary veins if needed (5,11). The left atrial wall is then attached to the pericardium in a circle around the pulmonary veins, avoiding stitches in the cut edges of the pulmonary veins (5).

The purpose of this approach is to reduce trauma to the pulmonary veins by reducing any stimulus for the regrowth of obstructive tissue (2). Unfortunately, the five-year survival and reoperation-free rate is only 50% (10,12). Other surgical interventions include balloon dilation and stent insertion (2). Some authors have argued for a role for balloon dilation in the management of resistant PVS lesions (13). Stent insertion has fallen out of favour, given the almost 100% restenosis rate (14,15). Pneumonectomy may be needed for refractory hemoptysis; lung transplantation has rarely been performed for severe pulmonary hypertension (2).

The prognosis for primary and secondary PVS remains guarded. If PVS is left untreated, and most or all of the pulmonary veins are affected, the condition is almost uniformly fatal; death is usually secondary to a pulmonary hypertension crisis, pulmonary or intercurrent infection, or hemoptysis (2). As a result of the raised awareness of PVS, more cases of milder forms are being diagnosed in relatively asymptomatic patients (2). Given that Holt et al (8) reported initial mean pulmonary arterial pressure to be an independent predictor of lung death in PVS patients, early diagnosis may lead to improved survival for these individuals. The authors also reported that patients presenting in infancy should be considered at high risk for mortality, regardless of the number of veins involved (8). Therefore, our patient had a significantly elevated risk of mortality given her young age at presentation and suprasystemic pulmonary pressures.

**SUMMARY**

PVS is a rare cause of pulmonary hypertension, and is associated with significant morbidity and mortality. Once the diagnosis is made, management is primarily surgical, with only a 50% success rate. It stands to reason that any treatment will have the best chance of success if completed before pulmonary hypertension becomes fixed. Early diagnosis depends on a high index of clinical suspicion.
