ABSTRACT

We report XMM-Newton observations of three FR II radio galaxies at redshifts between 0.85 and 1.34, which show extended diffuse X-ray emission within the radio lobes, likely due to inverse-Compton up-scattering of the cosmic microwave background. Under this assumption, through spectrum-fitting together with archival VLA radio observations, we derive an independent estimate of the magnetic field in the radio lobes of 3C 469.1 and compare it with the equipartition value. We find concordance between these two estimates as long as the turnover in the energy distribution of the particles occurs at a Lorentz factor in excess of \( \sim 250 \). We determine the total energy in relativistic particles in the radio emitting lobes of all three sources to range between \( 3 \times 10^{39} \) erg. The nuclei of these X-ray sources are heavily-absorbed powerful AGN.

Keywords: X-rays: galaxies — galaxies: jets — galaxies: high-redshift — X-rays: individual (3C 469.1, MRC 2216-206, MRC 0947-249).

1 INTRODUCTION

Emission from inverse-Compton scattered CMB (ICCMB) photons, in the form of diffuse, extended X-rays between the nucleus and radio hot spots, has been detected in a number of radio galaxies at cosmological distances (e.g., Fabian et al. 2003; Blundell et al. 2008; Erlund et al. 2008; Johnson et al. 2007) and at low redshift (e.g., Croston et al. 2005). ICCMB is a tracer of old, spent synchrotron plasma and its usefulness as a diagnostic of the magnetic field and electron energy distribution in AGN lobes stems from the fact that it is not redshift-dimmed (Schwartz 2002), unlike other sources of continuum X-ray emission.

Together with radio observations, ICCMB X-ray fluxes can be used to constrain the local magnetic field experienced by the radio-emitting plasma in the lobes of giant FR II (Fanaroff & Riley 1974) radio sources (see e.g., Erlund et al. 2006). Previous observations of ICCMB X-rays from radio galaxies have found deviations of the observed magnetic field from predictions based on equipartition arguments (see Croston et al. 2005, and references therein). While this can be resolved if the energy distribution turns over at the low-energy end (Blundell et al. 2006) at relatively high Lorentz factors (\( \gamma_{\text{min}} \sim 10^3 \)), estimates of the low-energy turn-over of the electron distribution in all observed radio galaxies and quasars have been largely inconclusive, with no consistent picture amongst the entire population of radio sources having yet emerged.

We present XMM-Newton observations of the FR II radio galaxy 3C 469.1, where we have detected extended X-ray emission, which is likely ICCMB. We extract and fit the X-ray spectrum for this source and show the photon spectral index, \( \Gamma \) to lie between 0.9 and 2.1, consistent with the radio synchrotron spectral index of 1.97 determined from NEIF archival radio photometry.

We use the calculated unabsorbed X-ray luminosity along with a new look at archival 1.5 GHz VLA data for this source to constrain the magnetic field, without assumptions of equipartition. Finally, we present X-ray observations of two more giant radio galaxies, MRC 2216-206 and MRC 0947-249, where ICCMB emission seems to also be apparent.

3C 469.1, MRC 2216-206 and MRC 0947-249 are located at redshifts of 1.336, 1.148 and 0.854 respectively, corresponding to linear scales of 8.6 kpc/\( z \) and as-

2 OBSERVATIONS AND DATA ANALYSIS

2.1 X-ray and radio imaging

Our XMM-Newton observations of 3C 469.1 were taken on 2008 September 29 and consist of 17.4 ks of EPIC-PN and 21.3 ks of EPIC-MOS data. Although the MOS data give roughly consistent results, they are much noisier and are not presented here. The EPIC-PN data were reduced using the standard XMM-SAS pipeline tasks EPCHAIN to give 443 ± 21 counts (of which 110 ± 4 are background) in the 0.3-10 keV band.

The source clearly shows extended emission at energies below

\( * \) Email: t.laskar@cfa.harvard.edu

\( \dagger \) http://nedwww.ipac.caltech.edu
1.2 keV (Fig. 1). We estimate the detection significance of the entire extended emission to be 10–σ and of the northernmost region of the quasi-linear structure to be 5–σ. Above 2 keV, a central core remains, which is consistent with being a point source. The extended linear morphology of the soft X-ray emission precludes it being due to hot cluster gas.

Radio data from all three targets came from the VLA archive. In the case of 3C 469.1, we used data from the A, B and C configurations (originally published by Kharb et al. 2008) to sample all the structure; for our other two targets only B-configuration data were available. Interference was excised from the data and 3C48 was used to set the absolute flux calibration; a number of rounds of phase self-calibration were performed, before a final iteration of phase and amplitude self-calibration. The final self-calibrated 1.5 GHz radio image for 3C 469.1 is shown in Figure 1. The cospatial nature of the radio synchrotron emission compared with the soft X-rays from this source suggests a fundamental connection between the emitting particle populations within the lobes.

The flux density of the extended radio emission, after subtracting the contribution from the hotspots, is about 300 mJy, with the North and South radio lobes contributing 0.256 Jy and 0.046 Jy, respectively. We note that the southern lobe is not detected in the soft X-ray image. A possible explanation for the extended emission is Inverse-Compton scattering of infrared photons from the host galaxy (Brunetti et al. 1997) into the line of sight by plasma within the lobes, which would produce more intense X-rays in the lobe directed away from the observer. However, in order for the energy density of the nuclear photons to be comparable to that of the microwave background 200 kpc into the lobes, the nucleus would be required to have an infrared luminosity of $10^{48}$ erg s$^{-1}$, which is implausible. Therefore, it is more likely that ICCMB is responsible for the observed X-ray flux. The discrepancy in the flux from the two lobes remains unresolved.

### 2.2 X-ray spectral analysis of 3C 469.1

The number of counts was insufficient to perform spectral fitting of the lobe and core regions separately (an attempt at fitting only the extended X-ray emission towards the North with a power law yielded a poorly-constrained photon index of $\Gamma = 3.2^{+1.2}_{-0.6}$). Therefore spectra of the entire source were extracted, with regions on the same chip selected as background. The spectrum was binned to 20 counts bin$^{-1}$ using GRPPHA and fitted in XSPEC v12.5.0 (Fig. 2).

The model used was a set of power laws in photon energy for both the extended and core emission, together absorbed photoelectrically by neutral hydrogen within our Galaxy, with allowance for additional soft-photon absorption within the host galaxy itself. Due to the poor constraints from the data, we assumed the two power law indices to be the same. Mathematically, the model of the X-ray flux density as a function of the photon energy, $E$:

$$M(E) = e^{-N_H^1 \sigma(E)} (K_1 E^{-\Gamma_1} + e^{-N_H^1 \sigma(E)} (K_2 E^{-\Gamma_2})). \quad (1)$$

Here $K_1$ and $K_2$ are the normalisations of the emission at 1 keV from the lobes and the core, respectively, $\Gamma_1$ and $\Gamma_2$ are the corresponding photon indices (set equal), $N_H^1$ is the absorbing column within our Galaxy along the line of sight to the source (1.38 × 10$^{21}$ cm$^{-2}$; Kalberla et al. 2005), $N_H^2$ is the extra absorbing column within the host galaxy, $\sigma(E)$ is the photo-electric cross-section (ignoring Thomson scattering) and $z = 1.336$ is the redshift. The best fit model ($\chi^2 = 13.9$ for 17 d.o.f.) is shown in Fig. 3 and the best fit values for this model are given in Table 1.
**Figure 3.** Best-fit model for XMM pn data for 3C 469.1. The model used (equation I) is two absorbed power laws with the same photon index, with one power-law component further attenuated by an absorbing column (estimated at 20.4$^{+18.3}_{-17.6}$ × 10$^{-22}$ cm$^{-2}$ at 90 per cent confidence) within the host galaxy.

**Figure 4.** $\chi^2$ contours at 68 per cent (innermost, black), 90 per cent (middle, red) and 99 per cent (outermost, green) confidence between the absorbing column in the host galaxy, $N_H^2$ and the power-law photon index, $\Gamma$ for the best fit model for the 3C 469.1 spectrum.

### Table 1. The constraints on the parameters for the best-fitting model (equation I).

| Parameter | Value | Nominal error |
|-----------|-------|---------------|
| $\Gamma_1 \equiv \Gamma_2$ | 1.5 | 0.6 |
| $N_H^2$ | 29 | ±18 |
| $K_1$ | 6.3 | $^{+1.5}_{-1.7}$ |
| $K_2$ | 24 | $^{+18}_{-20}$ |

The best fit model calls for a high absorption column in the nuclear component. A plot of the $\chi^2$ contours of $N_H^2$ versus $\Gamma$ (Fig. 4) shows the extra absorption to be statistically significant. After correcting for Galactic absorption, the total luminosity in the rest frame of the source in the rest-frame luminosity of the nucleus is 9.8 × 10$^{44}$ erg s$^{-1}$.

3 DETERMINATION OF MAGNETIC FIELD

For an electron population with a power-law distribution of energies, $N_\gamma(E) \propto E^{-\gamma}$ the synchrotron photons also follow a power-law spectrum with a spectral index, $\alpha = (n - 1)/2$. The ratio of the flux density from inverse-Compton emission at $\nu_c$ to the synchrotron flux density at $\nu_c$ is given by (see, e.g. Tucker 1977)

$$\frac{F_{\nu_c}}{F_{\nu_c}} = 2.47 \times 10^{-19} (5.23 \times 10^3)^{\alpha} \left(\frac{T}{1 \text{ K}}\right)^{3+\alpha} \left(\frac{\nu_c}{\nu_{cc}}\right)^{\alpha} \times$$

$$\left(\frac{b(n)}{a(n)}\right) \left(\frac{B}{1 \text{ Gauss}}\right)^{-\alpha} \left(\frac{\nu_c}{\nu_{cc}}\right)^{-\alpha},$$

where $B$ is the magnetic field strength in the radio-emitting lobes and $T$ is the temperature of the CMB at the redshift of the source, and the constants $a(n)$ and $b(n)$ have been tabulated by Ginzburg & Syrovatskii (1965) and Tucker (1977), respectively.

Taking the flux density of the inverse-Compton emission to be the X-ray flux density from 2 to 10 keV (rest frame), the flux density of the synchrotron emission to be 300 mJy at 1505 MHz, $\alpha = 0.97$, and $h\nu_c \approx 3$ keV yields a magnetic field of 12.5 $\mu$G. For comparison, taking $\alpha = 0.7$ in the above formula yields $B = 6.8 \mu$G, keeping all other values the same. It should be noted that this analysis requires the observed X-ray and radio fluxes to be co-spatial. If the X-ray emission is more extended than the radio, then one must use in the above formulae only that part of the X-ray flux which overlays the radio and vice-versa.

One can also determine the magnetic field by assuming the energy density in it to be the same as that of the electron population (see Longair 1994, eqn. 18.73). Taking the radio emitting lobes of 3C 469.1 to be a cylindrical region 640 kpc long and 140 kpc in diameter and assuming a minimum Lorentz factor of the electron population, $\gamma_{min} = 10^7$ gives an equipartition magnetic field of 9.0 $\mu$G. While this value is consistent with that determined from the X-ray and radio flux densities, the equipartition field depends on the volume of the region ($B \propto V^{-1.97}$ for $\alpha = 0.97$), which is difficult to determine with the low spatial resolution of XMM and given the low number of counts. With the assumed volume stated above, we must have $\gamma_{min} > 250$ for $\alpha \leq 0.97$ in order...
The volume emissivity in the ICCMB X-rays,

$$j(\nu) = 4.10 \times 10^{-40} T^3 (z) b(n) N \left( \frac{2.1 \times 10^{10}}{\nu} T(z) \right)^{(n-1)/2},$$

integrated over rest frame energies from 2-10 keV and equated to the X-ray luminosity of the lobes, yields the number density integrated over rest frame energies from 2-10 keV and equated to Lorentz factors of

$$\gamma = 10^{\epsilon z},$$

responding to Lorentz factors of 3.2 \times 10^4. Taking \(\gamma_{\text{min}}\) to be this value and assuming the electron energy spectrum to extend down to \(\gamma_{\text{min}} = 10^3\), the total energy in the plasma between \(\gamma_{\text{min}}\) and \(\gamma_{\text{max}}\) now allows for the determination of the total energy of the electrons responsible for the ICCMB. From the relation

$$\gamma = 1.89 \sqrt{1 + z} \left( \frac{\nu}{1 \text{ GHz}} \right)^{1/2} \left( \frac{B}{1 \mu\text{G}} \right)^{-1/2} 10^3,$$

the synchrotron emission at 14.9 GHz [Laing & Peacock 1980] corresponds to Lorentz factors of 3.2 \times 10^4. Taking \(\gamma_{\text{max}}\) to be this value and assuming the electron energy spectrum to extend down to \(\gamma_{\text{min}} = 10^3\), the total energy in the plasma between \(\gamma_{\text{min}}\) and \(\gamma_{\text{max}}\) is 8.1 \times 10^{59} \text{ erg}, which is comparable to that found by [Erlund et al. 2008] in the giant radio galaxy 6C0905+39 and by [Fabian et al. 2005] for HDF130 in the Chandra Deep Field North.

The combined pressure produced by relativistic electrons and the magnetic field is \(P/k_B = 5.2 \times 10^4 \text{ K cm}^{-3}\), which is comparable to that near the centre of a group of galaxies, but much larger than that of the IGM (\(\sim 0.3 \text{ K cm}^{-3}\)). Therefore whether the lobes continue to depend on the environment.

4 MRC SOURCES

We also obtained observations of giant radio galaxies MRC 2216-206 (z = 1.148, linear size 730 kpc [Kapahi et al. 1998]) and MRC 0947-249 (z = 0.854, linear size 530 kpc [Kapahi et al. 1998]) with XMM-Newton on 2008 May 03 and May 10, respectively, with corresponding exposure times of 22.6 ks (8.8 ks for 222 arcsec high and 183 arcsec wide. The X-ray images have been convolved with a Gaussian with FWHM of 3 pixels.

2 Good time remaining after filtering to remove flares and taking dead-time intervals into account

3 0.3 \( - \) 1.5 keV

are background, with 46 \pm 11 soft photons) for MRC 0947-249. Whereas at higher energies the X-ray images are more consistent with being point-like sources near the location of the corresponding optical host galaxy, indicated by crosses (Fig. 5 and 6), both sources show extended soft X-ray emission below 1.5 keV, which is plausibly due to ICCMB.

We note that the soft emission in MRC 2216-206 appears to extend beyond the location of the South-East radio hotspot. This could indicate an earlier outburst resembling the double-double radio galaxy phenomenon [Schoenmakers et al. 2000] but with the outerOLDER lobes only being detectable via ICCMB. However this extra emission, which consists of 30 counts in the 0.3 \( - \) 1.5 keV band, may also be due to a background AGN (at the corresponding flux level of \(6 \times 10^{-15} \text{ erg s}^{-1} \text{ cm}^{-2}\) in the 0.5 \( - \) 2.0 keV band for a photon index of \(\Gamma = 2.0\) for these 30 counts, we estimate a 30 per cent probability of a coincident background source in the regions of interest around our three sources using the source counts of [Hasinger et al. 2001]. We did not include the region beyond the radio hotspots in our analysis.

Spectral analysis of MRC 2216-206 was carried out exactly as for 3C 469.1, since a single-component power law fit gave an unphysically hard photon index of \(\Gamma = 0.5 \pm 0.35\). The two-component model yielded an extra host absorption of \(3.8 \pm 1.8 \times 10^{23} \text{ cm}^{-2}\) and a best fit energy index, \(\Gamma = 1.6^{+0.5}_{-0.4}\), consistent with a radio synchrotron index of \(\alpha = 1\) derived from NED archival radio photometry. The unabsorbed 2 \( - \) 10 keV luminosity of the nucleus is \(1.3 \times 10^{45} \text{ erg s}^{-1}\). The unfolded spectrum, along with the best fit model and residuals is shown in Fig. 7.

If we assume that the observed X-rays are inverse-Compton photons, we can follow equation 4 of [Erlund et al. 2005] to estimate the total energy in relativistic particles from the X-ray flux alone:

$$E_\gamma = \frac{3}{4} \frac{L_{44}}{\gamma_0 (1 + z)^3} \times 10^{64} \text{ erg},$$

where \(L_{44}\) is the X-ray luminosity in \(10^{44} \text{ erg s}^{-1}\) and \(\gamma_0\) is the typical Lorentz factor of the electrons up-scattering the CMB to X-rays. Setting \(\gamma_0 = 10\) gives \(E_\gamma = 5.7 \times 10^{58} \text{ erg}\) for MRC 2216-206. This is a lower limit to the total particle energy in the lobes of this object.

There were insufficient counts to fit the spectrum of MRC 0947-249. Instead, the soft photon count rate (\(4.6 \times 10^{-3}\) s\(^{-1}\)) was used along with a power-law model and an assumed photon energy index of \(\Gamma = 2.0\) to estimate the flux of the extended emission with PIMMS. The luminosity and total energy in relativis-
The spectrum is well fit (χ^2 = 13.9 for 17 d.o.f.) by a power law with a photon index consistent with the radio spectral index. Energy equipartition arguments agree with the magnetic field estimates made for 3C 469.1 based on the X-ray flux inferred to be ICCMB, provided γ_{min} is in excess of 250.

Further, we have presented XMM images of two more radio galaxies at cosmological distances, which show extended X-ray emission attributable to inverse-Compton CMB. The nuclei of all these sources have quasar-like luminosities and appear to be heavily absorbed powerful AGN, while the radio-emitting lobes have relativistic particles with similar total energies, ranging between 3 and 6 × 10^{59} erg. These values are enhanced if there is significant energy in protons.

It appears that ICCMB X-ray emission is indeed observable from giant radio galaxies at redshift z ~ 1. However, the cospatial nature of the X-rays with radio observations remains an important caveat in the determination of the magnetic field. Further observations of these sources with the finer PSF of Chandra would help solve this issue and observations with greater signal-to-noise would provide better constraints on the X-ray spectral index, which is essential for accurate determinations of γ_{min} and the establishment of the nature of the low-energy turn-over in aged AGN lobes.
