SURFACE MODELLING BY GEOID DETERMINATION FOR FLOOD CONTROL OF EWEKORO LIMESTONE DEPOSIT (NIGERIA)

Purpose. To determine the geoid heights from various control points of the quarry located in the northern and southern zones of the limestone deposit of the Lafarge WAPCO Cement Ewekoro in Ogun State, Nigeria.

Methodology. The GPS and levelling data were used to determine the geoid heights from various control points of the quarry located in the northern and southern zones of the limestone deposit. The geoid heights obtained from GPS-Levelling data were used for three surface models which are polynomial regression model, inverse distance model and nearest neighbour model. These models were used to crossvalidate the geoid heights for the control points.

Findings. The result shows that the deviations of the geoid heights for the GPS/Levelling and models are between 0.03 and 0.01 m respectively. The models were used to generate contour maps that reveal the better location where the flood can be channelled.

Originality. The results can be compared to the data obtainable during operations carried out in the quarry.

Practical value. The flood in the quarry face will be better controlled by creating a sump at the lowest point on the elevation maps and controlled drilling to give better aeration.

Keywords: Limestone deposit, GPS-levelling, geoid height, surface models, flood control

Introduction. The management of flood related issues in quarries is one of the most critical problems encountered during mineral exploitation especially in cases of incessant precipitation. An ineffective management could result in suspension of mining activities and even long term abandonment of the quarry in devastating situations. In 2007, Ewekoro quarry suffered disruption of operation as a result of flooding due to the location of the deposit and this reduced the supply of raw material to the production factory.

The distribution of mine flooding is influenced by one global factor. It is the relationship of the ore body to the surface topography. This relationship expresses itself in several ways. The primary influence is on the location and direction of mining [1]. In order to mine from any mining sites with due respect to the natural occurrence like flood, then the topography of the site must be taken so that water would freely drain from the mines.

The expanding uses of geodetic control in support of spatial information systems demand the adoption of reliable procedures to support geo-referencing of spatial data and Geographical Information System (GIS) activities. Therefore, the continuing evolution of Global Positioning System (GPS) and Geographical Information System (GIS) hardware and software as well necessitates the adoption of standards and specification in planning, surveying, methodologies, and implementation of both systems. The links between GIS software and the spatial data produced by GPS or levelling techniques develop the geo-referencing process and the specifications adopted to ensure the given level of the accuracy [2]. A number of factors have led to an increasing need for geo-referencing and spatial data products on a common reference frame that extends across the whole globe. These factors include growing reliance on satellite positioning systems and development of satellite based mapping systems in order to achieve higher resolution [3].

In order to produce or update spatial data related to surveying applications, a network of control points is necessary. Such a network consists of a number of points spread across the area under consideration. By referencing spatial data to such network, the resulting data and information from multiple local surveying activities can be accurately connected [4].

The impact of the GPS is undeniable. In the span of just a few years GPS has become the leading positioning technology [5]. This revolution has not been confined to surveying community, but has extended into mapping, navigation, and GIS applications. Many of these applications require accurate vertical positioning. Generally, coordinates determination from GPS measurements uses the known positions of satellites and the measured distance between satellites and the known points. It is commonly considered as a three-dimensional system (Latitude, Longitude, and ellipsoidal height). But, the heights obtained from GPS are typically heights above an ellipsoid model of the earth [6]. It is a geodetic height which is purely geometrical quantity, and represents the length of the normal to the reference ellipsoid between the ellipsoid and the point of interest. These GPS ellipsoidal heights are not consistent with levelled heights above mean sea level (MSL), often known as orthometric height [7]. The orthometric height is defined as the length of the plumb-line (a line that is always normal to the equipotential surface of the gravity field) between the geoid and the point of interest and as such is intimately related to the gravity field of the earth (Weikko and...
Company acquired it. Lafarge WAPCO has three plants in Nigeria with their presence in over 64 countries. The cement company WAPCO Nigeria Plc, which is a subsidiary Lafarge Company estimation.

In order to convert the high-precision ellipsoidal heights to orthometric heights from these two methods were used to calculate the geoid undulation. This research was carried out to design a better way of controlling flood and reserve estimation. This study was carried out to design a better way of controlling flood and reserve estimation.

The study area belongs to Lafarge cement WAPCO Nigeria Plc, which is a subsidiary Lafarge Company with their presence in over 64 countries. The cement company formerly bear the name WAPCO Plc but was changed to Lafarge Cement WAPCO Nigeria Plc in 2008 after the Lafarge Company acquired it. Lafarge WAPCO has three plants in Nigeria, one in Shagamu and two in Ewekoro with current production capacity of 4.5 million metric tons per year. The study area lies within Ogun State, which is bounded in the west by the Benin Republic, in the south by Lagos State, in the north by Oyo and Osun States, and in the east by Ondo State. It occupies a total area of 16 400 km². Ewekoro is the host to Lafarge West African Portland Cement quarry and lies between longitude 3° 05´ to 3° 15´E and latitudes 6° 40´ to 6° 55´N.

Overlying the Abeokuta Group conformably is the Imo Group, which is comprised of shale, limestone and marls. The two-lithostratigraphic units under this group are Ewekoro Formation and Akinbo Formation. Adegoke (1977) described the formation as consisting of shaly limestone and about 12.4 m thick which tends to be sandy and divided into three microfacies. This was further modified and fourth unit was proposed. It is Paleocene in age and is associated with shallow marine environment due to abundance of coralline algae, gastropods, pelecypods, echinoid fragments and other skeletal debris. Akinbo Formation lies on the Ewekoro Formation and it is comprised of shale, glauconitic rock bank, and gritty sand to pure grey and with little clay. Lenses of limestone deposit from Ewekoro Formation grades literally into the Akinbo shal very close to the base. The base is characterized by the presence of a glauconitic rock. The age of the formation is Paleocene to Eocene.

The geoid height (or geoid undulation) can be defined as the separation of the reference ellipsoid with the geoid surface measured along the ellipsoidal normal. The classical Gauss-Listing definition of the geoid is given as an equipotential surface of the Earth’s gravity field that coincides with the mean sea level [16]. Today, it is well known that this is not a strictly correct definition as the equipotential surface is the surface by up to two meters due to various oceanographic phenomena, such as variable temperature, salinity, instantaneous sea surface topography, and so on [16]. Ellipsoidal heights obtained with GPS do not reflect the natural situation. So, they cannot meet precision of practical needs related to heights. However, orthometric heights are more compatible with physical event and so, they are used successfully in solving many problems related to heights in practice. But obtaining orthometric heights with traditional surveying techniques or using inclinometers or extensometers. Examples of successful small scale monitoring using GPS can be found for bridges [11], buildings [12], volcanoes [13], local and regional ground movements due to seismic events [14], and ground subsidence [15].

Ellipsoidal heights obtained with GPS do not reflect the natural situation. So, they cannot meet precision of practical needs related to heights. However, orthometric heights are more compatible with physical event and so, they are used successfully in solving many problems related to heights in practice. But obtaining orthometric heights with traditional surveying techniques or using inclinometers or extensometers. Examples of successful small scale monitoring using GPS can be found for bridges [11], buildings [12], volcanoes [13], local and regional ground movements due to seismic events [14], and ground subsidence [15].

In order to convert the high-precision ellipsoidal heights to orthometric heights, as is required for engineering purposes, the determination of the geoid is necessary. Because the relation between ellipsoidal and orthometric heights involves the geoid undulation [17]. When accurate heights are achieved, then the data can be used to design flood control and reserve estimation.

The samples collected from the field are both GPS coordinates of the quarry bench and the levelling coordinates of the same respective area. The heights from these two methods were used to calculate the geoid of the area using the formula

\[ N = h - H, \]

where \( N \) is the geoid height; \( h \) is the ellipsoidal height; \( H \) is the orthometric height.
Determination of geoid heights of test points in different geoid models. Geoid undulation values of 100 selected test points were calculated in Polynomial Regression, Nearest Neighbour and Inverse Distance global geoid models. To obtain the geoid heights firstly, the height anomaly values of points were interpolated according to each model with the program harm.exe of GOLDEN software (Surfer 9) package by using the known latitude, longitude and heights of points. After that, having applied the correction to the determined height anomalies, geoid heights \((N)\) were calculated. \(N\) geoid heights were determined according to the different specified models.

Results. Statistical Analysis. The geoid heights are calculated from the differences in the ellipsoidal and orthometric heights for the two zones. The adjusted readings are presented in Table 1. The post-maps of the GPS reading for the northern and southern zone of the quarry surface are presented below.

Table 2 gives the abridge result of the calculation from the polynomial regression, inverse distance and the nearest neighbour model as used in this work. The result covered 100 control points for both the northern and the southern zones area under consideration. Tables 3–7 and 8 show the statistical analysis of the models as distributed in dispersion.

Comparison of the surface models. Tables 9–13 and 14 show the comparison of the differences in the GPS/Levelling geoid and the geoid from the other models. The Range, Minimum, Maximum, Mean and Standard Deviation of these differences are shown as well.

Surface images generated from the models. Fig. 3 shows the images of the contour maps obtained from the Inverse Distance Model while Fig. 4 shows that obtained from the Polynomial model and Fig. 5 shows that obtained from the Nearest Neighbour Model. Each model figures are presented in three maps that represent the contour maps according to the point of references 25, 50 and 100 for the Northern Zone in that order. Also Figs. 6, 7 and 8 show the contour maps obtained from the Inverse Distance Model, Polynomial regression

Figs. 9 and 10 show the contour maps with elevations of geoid obtained from the Inverse Distance and Nearest Neighbour Models from both the Northern and Southern zones.

From Figs. 9 and 10, which are obtained from the Inverse Distance and Nearest Neighbour Models, the quarry face can be prevented from flooding by channeling the sump for each quarry face at the base area of the map (labelled part A). The Ewekoro quarry whose operation has reached the second bench and still progressing downward is prone to flooding during the raining seasons, which can bring about halt to the quarry operation and this in turn can hinder the cement production operation. From the elevation plot of the readings from the quarry pit the flood prone areas could be discovered for adequate measures and preventions.

Model and Nearest Neighbour Model for the Southern Zone. Figs. 9 and 10 show the contour maps with elevations of geoid obtained from the Inverse Distance and Nearest Neighbour Model from both the Northern and Southern zones. **Flood control.** From Figs. 9 and 10, which are obtained from the Inverse Distance and Nearest Neighbour Models, the quarry face can be prevented from flooding by channeling the sump for each quarry face at the base area of the map (labelled part A). The Ewekoro quarry whose operation has reached the second bench and still progressing downward is prone to flooding during the raining seasons, which can bring about halt to the quarry operation and this in turn can hinder the cement production operation. From the elevation plot of the readings from the quarry pit the flood prone areas could be discovered for adequate measures and preventions.
Fig. 4. Contour maps of geoid obtained from the Polynomial Regression Model (Northern Zone):
\[ \text{a – 25 – control points; b – 50 – control points; c – 100 – control points} \]

Fig. 5. Contour maps of geoid obtained from the Nearest Neighbour Model (Northern Zone):
\[ \text{a – 25 – control points; b – 50 – control points; c – 100 – control points} \]

Fig. 6. Contour maps of geoid obtained from the Inverse Distance Model (Southern Zone):
\[ \text{a – 25 – control points; b – 50 – control points; c – 100 – control points} \]

Fig. 7. Contour maps of geoid obtained from the Polynomial Regression Model (Southern Zone):
\[ \text{a – 25 – control points; b – 50 – control points; c – 100 – control points} \]
Conclusion. From the result obtained, the root mean square (RMS) values obtained from the control points of the southern zone are 0.31, 0.30, 0.27 and 0.27 for the geoid heights of all methods used, while 0.32, 0.31, 0.32 and 0.32 are obtained from the control points in the northern zone. These RMS values are very close in figure and it validates the geoid heights obtained from orthometric and ellipsoidal heights. In application it can be seen easily that RMS errors of this methods are very high. As a result of all evaluation polynomial regression, multi-quadratic and triangulation-interpolation methods can be used for geoid surface; these models equally promote enough accuracy for determination of orthometric heights from GPS alongside with Inverse distance and nearest neighbour models.

The most suitable geoid models for this quarry are the Inverse Distance and the Nearest Neighbour model. The deviation of these geoid models from GPS/levelling geoid model is ± 0.019 and ± 0.13 m at the northern and the southern zones. The value is smaller than root mean square values related to other global geoid models. It is thought that the cause of the situation is development of technology and better quality of data. When the distribution of differences in the quarry was examined, it was seen that there were bigger differences in the coast of the Polynomial Regression Model.

The elevation map obtained from different models heights, the sump location can be easily sited at the lowest elevation of the quarry face, with the overhead pressure, the rate of sipping of the ground water or the precipitation, the require pump power to discharge the water determined, the recommended pump machine can be acquired. Also the drilling of the blast-hole can be designed to give better aeration of water from the face to the sump.

Recommendations. The Mine Surveyors with Engineers should take note of the elevation diagrams and plan accordingly to promptly determine how the reserve is being depleted and also to construct accurate road network and precise sump sites that would not obstruct smooth flow of mining operations. Also the geological survey to increase the life of the deposit should continue.

Future research should look to application of geostatistical simulation in estimating the potential of the limestone reserve.
as well as its variability. Moreover, the application of artificial intelligence i.e. neural networking should also be considered for estimation and prediction purposes of the reserve.

Мета. Визначення висоти геоїда в різних контрольних точках кар’єра, розташованих у північній і південній зонах вапнякового родовища, що розробляє компанія Lafarge WAPCO Cement Ewekoro у штаті Огун, Нігерія.

Методика. Для визначення висот геоїда в різних контрольних точках кар’єра, розташованих у північній і південній зонах вапнякового родовища, були використані дані GPS і горизонтальної зйомки, що дозволили побудувати три моделі поверхні: поліноміальну модель рессії, модель інверсної відстані і модель найближчого сусіда. Дані моделі були використані для перехресної перевірки висоти геоїда в різних контрольних точках.

Результати. Результати дослідження показали, що розбіжність між значеннями висот геоїда, отриманими за допомогою GPS-горизонтальної зйомки та шляхом моделювання, знаходяться у межах 0,03 та 0,01 м відповідно. На основі моделей були складені контрольні карті з позначеннями найкращими локаціями для відводу паводків.

Наукова новизна. Результати зіставлені з даними, що можна отримати у процесі експлуатації родовища.

Практична значимість. Підтоплення забою кар’єра можна краще регулювати, якщо встановити дренажні відстійники у навігувальній точці кар’єра і провести коректні регулювання бурильних для забезпечення кращої відпрацювання.

Ключові слова: вапнякове родовище, GPS-горизонтальна зйомка, висота геоїда, моделі поверхні, боротьба з підтопленням
