SUMMARY

Singlet fission is known to improve solar energy utilization by circumventing the Shockley-Queisser limit. The two essential steps of singlet fission are the formation of a correlated triplet pair and its subsequent quantum decoherence. However, the mechanisms of the triplet pair formation and decoherence still remain elusive. Here we examined both essential steps in single crystalline hexacene and discovered remarkable anisotropy of the overall singlet fission rate along different crystal axes. Since the triplet pair formation emerges on the same timescale along both crystal axes, the quantum decoherence is likely responsible for the directional anisotropy. The distinct quantum decoherence rates are ascribed to the notable difference on their associated energy loss according to the Redfield quantum dissipation theory. Our hybrid experimental/theoretical framework will not only further our understanding of singlet fission, but also shed light on the systematic design of new materials for the third-generation solar cells.

INTRODUCTION

Singlet fission has recently attracted extensive attention from both experimentalists and theoreticians and has been identified in various materials, including small molecules, polymers, and even inorganic crystals. The singlet fission process is characterized by the conversion of a singlet exciton into two correlated triplet excitons, which can then dissociate into two individual triplet excitons. This process is known to improve solar energy utilization by circumventing the Shockley-Queisser limit for solar energy utilization.

Previous studies were primarily focused on the first step, where the singlet exciton is converted into a correlated triplet pair. However, the mechanisms of the triplet pair formation and subsequent quantum decoherence are still not well understood.

where $S_0$ is a ground state, $S_1$ is a singlet excited state, and $k_F$ and $k_Q$ denote the rate constants for the formation of $\text{1(T1,T1)}$ and its quantum decoherence, respectively. Despite recent tremendous efforts, the mechanisms of these two constituent steps of singlet fission ($\text{Bakulin et al., 2016; Chan et al., 2011, 2012; Miyata et al., 2017; Musser et al., 2015; Stern et al., 2017}$) are ascribed to the notable difference on their associated energy loss according to the Redfield quantum dissipation theory.
could be mediated by fusion of two triplets via triplet-triplet annihilation (Yong et al., 2017), thereby
decreasing the photon-to-exciton conversion efficiency. The fundamental driving force for the quantum
decoherence of $^1(T_1T_1)$ is its interaction with its dissipative environment, which is typically described by a
thermalized phonon path at finite temperature (Tao, 2014). This system-environment interaction varies
greatly from amorphous, or polycrystalline, to ordered crystalline structures. Singlet fission materials in
the form of single crystal are anticipated to exhibit pronounced collective characteristics in molecular vibra-
tions because of their ordered crystalline structures.

In this work, we investigated the quantum decoherence of $^1(T_1T_1)$ states in single crystalline hexacene by
polarized transient absorption spectroscopy in conjunction with ab initio quantum mechanics simulations.
Our results showed that both $^1(T_1T_1)$ and $T_1+T_1$ states are of anisotropic origin owing to triplet Davydov
splitting in hexacene, leading to distinctive quantum decoherence rates along crystal $a$ and $b$ axes. This
notable anisotropy can be principally ascribed to the difference on the energy gap between $^1(T_1T_1)$ and
$T_1+T_1$ according to the Redfield quantum dissipation theory (Ishizaki and Fleming, 2009). Moreover,
through our functional mode analysis, the anisotropic quantum decoherence is predominantly driven by
some slow phonon modes with an effective frequency $\omega_p < 50$ cm$^{-1}$.

**RESULTS**

**Singlet Davydov Splitting in Hexacene**

Hexacene single crystals used in our experiments were grown with physical vapor transport by following a
recently developed method (Laudise et al., 1998; Watanabe et al., 2012). Their typical lateral size was on the
order of 20 $\mu$m $\times$ 40 $\mu$m (Figure 1A), whereas their thickness was estimated to be 0.5 $\mu$m as detailed in Sup-
plemental Information. The triclinic unit cell of hexacene shown in Figure 1B is defined by experimental in-
plane crystal lattice constants (Watanabe et al., 2012) of $a = 7.673$ Å (long axis) and $b = 6.292$ Å (short axis)
(Yamagata et al., 2011). A home-built microscopy was coupled with a tungsten-halogen light source for po-
larization-dependent optical transmission measurements of hexacene single crystal (Figure S1), and its po-
larization-resolved linear absorption spectra for the $ab$ plane is presented on Figure 1C. Interestingly, the
polarized measurements exhibit different absorption features along these two lattice axes. The lowest resonant peak at 835 nm was assigned to be the transition along the short $b$ axis and is called $b_1$. On
the other hand, the lowest transition at 761 nm was attributed to the transition along the long a axis and is named a$_1$. Apparently, b$_1$ is redshifted by 144 meV (1.160 cm$^{-1}$) with respect to a$_1$. This notable energy difference is due to the splitting of electronic excitations, the so-called singlet Davydov splitting (Davydov, 1948, 2013) that stems from dipole-dipole interactions of two non-equivalent molecules in a hexacene unit cell (Chernikov et al., 2014; Hestand et al., 2015).

Calculated Anisotropic Energy Levels in Hexacene Single Crystals

To explore the energy levels of all singlet-fission participating states in single crystalline hexacene, we performed computer simulations under periodic boundary conditions. Specifically, the single crystalline hexacene was modeled as a 9$\times$9$\times$3 supercell with a total of 20,412 atoms (Figure 2A). For a compromised balance between numerical efficiency and physical accuracy, the hybrid quantum mechanics/molecular mechanics approach (Warshel and Levitt, 1976) was adopted. A detailed description of the computational calculations can be found in Supplemental Information. As shown in Figure 2B, we denote the ground state, singlet excited state, charge-transfer state, correlated triplet pair, and uncorrelated triplet dimer as $S_0S_0$, $S_1S_0$, CT, $T_1T_1$, and $T_1 + T_1$, respectively, and their constituent spin configurations were illustrated in our previous studies (Elenewski et al., 2017a, 2017b). Geometry optimization was carried out on all spin states before their relative energies are determined. The only exception is $S_1S_0^*$, which assumes the same geometry as $S_1S_0$, such that $\Delta E(S_1S_0 \rightarrow S_1S_0^*)$ reflects the vertical optical gap of hexacene crystal. In particular, the linear-response time-dependent density functional theory (Casida and Huix-Rotllant, 2012) was utilized to delineate the $S_1S_0$ and $S_1S_0^*$ states, whereas the constrained density functional theory (CDFT) (Kaduk et al., 2012) was used to construct the reference orbitals needed for the multi-configurational CT, $T_1T_1$, and $T_1 + T_1$ states. As for the $T_1 + T_1$ dimer, a correction term of $-k_B T \ln(3 \times 3) \approx -56$ meV was added to account for the electronic spin entropy. Interestingly, we found that the $T_1T_1$ and $T_1 + T_1$ states along the short b axis are more thermodynamically stable than their counterparts along the long a axis, suggesting possible directional heterogeneity of quantum decoherence.

Spectroscopic Signatures of Triplet Davydov Splitting

Transient absorption spectroscopy is a proven tool to investigate singlet fission in solution and in thin film. We have designed and constructed a polarization-resolved transient absorption microscopy to examine anisotropic singlet fission in hexacene single crystals. A detailed description of our experimental setup is presented in Figure S1. In short, a regenerative amplifier Ti:Sapphire laser system operating at 795 nm and 1 kHz repetition rate was used for our measurements. A small portion of the laser pulse was taken as a pump light, and its fluence on samples was kept below 200 $\mu$J/cm$^2$ to avoid exciton-exciton...

Figure 2. Supercell and Energy Diagram of all Spin States for Hexacene Single Crystal

(A) 9$\times$9$\times$3 supercell of a hexacene single crystal. The tetramer designated as the singlet fission reaction center is highlighted. The molecular pair along the crystal a axis is colored blue, whereas the one along the crystal b axis is colored red. Moreover, all nearest neighbors of the tetramer are colored green.

(B) Energy diagram of all spin states participating in the single-fission process. The ground state, singlet excited state, charge-transfer state, correlated triplet pair, and uncorrelated triplet dimer are denoted as $S_0S_0$, $S_1S_0$, CT, $T_1T_1$, and $T_1 + T_1$, respectively. Their subscripts of a and b refer to the corresponding crystal axes. For instance, $T_1T_1$ represents a correlated triplet pair whose constituents are along the [100] crystal axis.
annihilation (Figure S3) by using a half-wave plate and a polarizer. Another small part of the laser pulse with a pulse energy of ca. 1 μJ was focused onto a sapphire crystal to generate white light supercontinuum as a probe. The pump and probe beams were combined to become collinear with a pellicle beam splitter. They were then focused onto samples through a 10× microscope objective. The polarizations of the pump and probe beams were independently adjusted with two individual half-wave plates.

To explore anisotropic spectral kinetics in hexacene single crystals, polarization-resolved transient absorption measurements were performed along both axes using a pump along b axis under the near lowest photo-excitation of 795 nm. Their results were presented as pseudo-color plots of transient absorption spectra (∆T/T) along b axis (Figures 3A and 3B) and a axis (Figures 3C and 3D). We chose two different color scales to highlight the difference on relaxation between the perturbed ground state and the newly populated excited states. The strong positive changes in ∆T/T between 729 and 620 nm were primarily due to the ground state bleaching and recovery. As expected, these positive responses are similar to those of the linear absorption spectra in hexacene as shown in Figure 1C. The negative spectral changes in ∆T/T between 496 and 620 nm were attributed to the photo-induced absorption of the excited states (Figures 3E and 3F). The transient spectra along both axes have broad, featureless, and short-lived bands from 496 to 577 nm (Figures 3E and 3F). The fast process dominated in this spectral region can be ascribed to the excited state absorption S1 to a higher singlet state Sn (S1 → Sn). By contrast, long-lived peaks appear in the range between 590 and 620 nm, as well as in the range between 508 and 544 nm. The latter even overlaps with the short-lived bands. We attributed these long-lived peaks to triplet transitions in hexacene. Again, a strong anisotropy was observed on the triplet transitions. The peak along b axis is at 599 nm, whereas the one along a axis is redshifted by 9 nm. Since the redshift is an indicator of triplet Davydov splitting, we expect a coexistence of two kinds of triplet excitons with a splitting energy of 30 meV. Note that the correlated triplet pair, (T1a + T1b), is a dark state in our case and did not show appreciable spectral feature in the transient spectra. Therefore, the 9-nm redshift must be induced by the energy difference between the decoupled triplet dimers, i.e., T1a + T1a and T1b + T1b. Interestingly, T1b + T1b was found to be energetically more stable than T1a + T1a probably due to the stronger Davydov splitting between two spatially closer
triplet excitons. Nevertheless, the long-lived spectral features between 500 and 620 nm were assigned to the $T_1/T_n$ transitions along both axes (Busby et al., 2014; Lee et al., 2013).

Moreover, we measured the anisotropic transient spectra using pumps along both axes to further verify the independence of triplet Davydov splitting on pump polarization. The independence was confirmed by Figure S4, which does not manifest appreciable change when the pump polarization is varied. Furthermore, we changed the excitation wavelengths to 400 nm and again observed distinctive triplet Davydov splitting (Figure S12). Therefore, the anisotropy of the triplet states and their derivatives is an intrinsic property of crystalline hexacene regardless of external electromagnetic perturbations.

**Singlet Fission Kinetics along the Long and Short Crystal Axes**

Figure 4 shows kinetic traces of hexacene in terms of $\Delta T/T$ after pumps are applied along b axis with the following wavelengths: (1) 525 ± 18.0 nm for $S_1 \rightarrow S_0'$; (2) 599 ± 8.7 nm for $T_{1b} \rightarrow T_{1nb}$; (3) 608 ± 9.0 nm for $T_{1a} \rightarrow T_{1na}$. A kinetic model (Johnson et al., 2010; Monahan et al., 2017; Wan et al., 2018) was used to derive the generation and dissociation rates for the $[^{1}(T_1T_1)]$ state from the experimental data shown in Figure 4. The detailed fitting procedure can be found in Supplemental Information. A global fitting of the kinetic traces affords the formation ($k_F$) and decoherence ($k_Q$) rates along b axis as $k_{F,b} = 4.5 \pm 0.2$ ps$^{-1}$ and $k_{Q,b} = 6.7 \pm 0.2$ ps$^{-1}$; and the a axis as $k_{F,a} = 5.0 \pm 0.2$ ps$^{-1}$ and $k_{Q,a} = 3.3 \pm 0.2$ ps$^{-1}$, respectively. The instrumental response function was 130 fs.

**DISCUSSION**

Our studies of single crystalline hexacene have three main traits: (1) a large triplet Davydov splitting of 30 meV; (2) a homogeneous $[^{1}(T_1T_1)]$ formation rate regardless of molecular directionality; (3) a notable anisotropy of $[^{1}(T_1T_1)]$ quantum decoherence rate. We have also proposed a unified vibronic model for singlet fission by treating the formation of a correlated triplet pair and its quantum decoherence on the same footing using our non-adiabatic functional mode approach (Chen, 2014; Elenewski et al., 2017b). As clearly depicted in Scheme 1, the optical excitation results in anisotropic structural and dynamical properties for both the $[^{1}(T_1T_1)]$ and $T_1 + T_1$ states, allowing us to gain more insights into the intrinsic directional heterogeneity of triplet excitons in single crystalline hexacene.

**Formation of $[^{1}(T_1T_1)]$ Directly from $[^{1}(S_1S_0)]^*$**

The formation of $[^{1}(T_1T_1)]$ is generally considered as the rate-determining step of singlet fission under the assumption of ultrafast quantum decoherence of $[^{1}(T_1T_1)]$. Surprisingly, our results show that the formation...
of $^1(T_1T_1)$ outpaces its quantum decoherence in hexacene, making the overall singlet fission rate predominantly decided by the latter. More interestingly, the formation rates of $^1(T_1T_1)$ were found to be similar along $b$ axis ($k_{F,bb} = 4.5 \pm 0.2 \text{ ps}^{-1}$) and $a$ axis ($k_{F,aa} = 5.0 \pm 0.2 \text{ ps}^{-1}$). As previously discussed, the formation of $^1(T_1T_1)$ could proceed through the direct, the CT-mediated, and the sequential mechanisms. To reconcile which mechanism is responsible for the fast and isotropic formation of $^1(T_1T_1)$ in hexacene, we employed our functional mode vibronic theory that has been successfully applied to investigate singlet fission in tetracene and pentacene (Elenewski et al., 2017a, 2017b). If the direct mechanism is followed, $^1(T_1T_1)$ is formed without the aid of any CT intermediate. By contrast, the sequential mechanism demands a thermodynamically stable CT state with an energy lower than the hot $^1(S_1S_0)^*$. Similarly, the mediated mechanism entails a virtual CT state, whose energy should be close to $^1(S_1S_0)^*$ for an ideal vibrational wave-function mixing between them. Since our calculated energy diagram in Figure 2 manifests a relatively large energy gap of over 0.25 eV between the CT and $^1(S_1S_0)^*$ states, both the sequential and mediated mechanisms should be effectively blocked. In this regard, we assume that the $^1(T_1T_1)$ pair production in single crystalline hexacene only proceeds through the direct mechanism (Elenewski et al., 2016, 2017b):

$$k_F = \frac{J^2}{h^2} \int_{-\infty}^{+\infty} e^{i\Omega \tau} e^{-\frac{\Omega^2 \tau^2}{2\lambda^2}} e^{-n(0) \hbar \Omega} e^{-\frac{\Delta G_0}{k_B T}} d\tau$$  

(Equation 2)

where $J$ is the electronic strength between $^1(S_1S_0)^*$ and $^1(T_1T_1)$, $\Delta G_0 = E_{S_1S_0} - E_{T_1T_1}$ is the driving force of singlet fission, $\lambda$ is the associated reorganization energy, $\Omega$ is the angular frequency of the effective singlet-fission driving vibrational mode, $\Gamma$ is its thermal relaxation rate, and $n(0) = E_{inc}/E_{inc}/h\Omega$ is the optically populated initial vibrational quanta where $E_{inc}$ is the incident light energy, which is 795 nm in the present study. We can then apply Equation 2 to calculate the $^1(T_1T_1)$ formation rate $k_F$ under non-thermalized condition. It was found that $k_{F,aa}$ of 0.93 ps$^{-1}$ is nearly the same as $k_{F,bb}$ of 0.83 ps$^{-1}$, in spite of a modest disparity in energetic parameters such as $\Delta G_0$ and $\lambda$. The diminished difference on $k_F$ along $a$ and $b$ axes primarily arises from their fast $\Omega$s, whose zero-point energies become much more overwhelming for vibrational quantum tunneling. As suggested by Busby et al., 2014, almost all singlet excitons in hexacene crystal undergo singlet fission, resulting in a triplet quantum yield of nearly 200% that also affords a
negligible fluorescence quantum yield. If so, the overall decay rate, $k_D$, of $^{1}\text{S}_1\text{S}_0^*$ is simply $k_F + \Gamma$, leading to $k_{D, aa}$ of $1.86\text{ ps}^{-1}$ and $k_{D, bb}$ of $2.08\text{ ps}^{-1}$. These computed rates are in good agreement with those obtained from our experimental measurements, indicating a direct formation of $^1\text{T}_1\text{T}_1$ from the vibrationally “hot” $^1\text{S}_1\text{S}_0^*$ in hexacene. In fact, previous studies of hexacene thin films attributed a slower singlet fission to multi-phonon relaxations, as compared with pentacene and tetracene (Busby et al., 2014). For example, ultrafast vibronic spectroscopies of pentacene and its derivatives showed that the singlet fission process is a single-molecular internal conversion via a conical intersection due to strong coupling between nuclear and electronic motions (Musser et al., 2015). As a result, the thermal relaxation of the $^1\text{S}_1\text{S}_0^*$ state should be taken into account when its decay rate is probed by transient spectroscopy techniques.

### Anisotropic Nature of $\text{T}_1 + \text{T}_1$ and $^1\text{T}_1\text{T}_1$

Triplet Davydov splitting exhibits a difference in energy as high as $30\text{ meV}$ along the $a$ and $b$ axes in hexacene single crystals, indicating that the $\text{T}_1 + \text{T}_1$ states remain strong dipole-dipole interactions in the anisotropic environment. The energy level of $\text{T}_{1b} + \text{T}_{1b}$ is lower than that of $\text{T}_{1a} + \text{T}_{1a}$ in the case of hexacene. This energy alignment is opposite to that of pentacene (Figure S5) and tetracene (Schwoerer and Bi-Rech, 2014), both of which have $\text{T}_{1b} + \text{T}_{1b}$ higher than $\text{T}_{1a} + \text{T}_{1a}$ as reported. Since the anisotropic lowest spin-correlated triplet $\text{T}_1 + \text{T}_1$ states arises from the decoherence of $^1\text{T}_1\text{T}_1$, it is legitimate to surmise that the $^1\text{T}_1\text{T}_1$ states should be anisotropic in hexacene single crystals. We further hypothesized that the energy level for $^1\text{T}_{1a}\text{T}_{1a}$ is lower than that for $^1\text{T}_{1b}\text{T}_{1b}$ in hexacene single crystals from the measured triplet Davydov splitting.

To reveal the nature of the anisotropic $^1\text{T}_1\text{T}_1$ and $\text{T}_1 + \text{T}_1$ states, we need to address the anti-ferromagnetic electron correlation in acenes as revealed by a complete active space simulation using the density matrix renormalization group algorithm (Hachmann et al., 2007). This anti-ferromagnetism was later corroborated by a spin-polarized density functional theory study (Jiang and Dai, 2008), which discovered spatially separated magnetizations in acenes. Similarly, electron spins in hexacene favor anti-ferromagnetic correlation, resulting in the notable presence of diradical covalence resonance structures. For example, a pair of adjacent hexacene molecules along $a$ axis had been extracted from the crystal structure before a complete active space self-consistent field calculation (Aquilante et al., 2016) with an active space of CAS(6,6) was conducted to reveal an enthalpy difference, $E_{\text{T}_{1a}\text{T}_{1a}} - E_{\text{T}_{1b}\text{T}_{1b}}$, of $16.7\text{ meV}$. In fact, a similar value of $13.5\text{ meV}$ was also achieved by our employed CDFT method that had been demonstrated to achieve a comparable accuracy against the multireference configuration interaction MRCl + Q level of theory on polyacenes (Kubas et al., 2014). Since a $\text{T}_1 + \text{T}_1$ dimer has less anti-ferromagnetic characteristics than its parental $^1\text{T}_1\text{T}_1$ pair in spite of more available spin microstates, its relative energetic stability is determined by a direct competition between enthalpy and entropy, i.e., $E_{\text{HS} -15}$ versus $k_B\text{Tnin}$. It turns out that entropy is a more dominant factor than enthalpy for crystalline hexacene at room temperature, making $\text{T}_1 + \text{T}_1$ thermodynamically more stable than $^1\text{T}_1\text{T}_1$ as shown in Figure 2. By the same token, the $^1\text{T}_{1a}\text{T}_{1a}$ pair is expected to have a higher energy than its counterpart along axis $b$ owing to diminished anti-ferromagnetic coupling strength over distance. Nevertheless, the difference on the spin-flip energy between the two axes is not strong enough to override their gap on the $^1\text{T}_1\text{T}_1$ pair, thus sustaining the relative stability of $\text{T}_{1b} + \text{T}_{1b}$ over $\text{T}_{1a} + \text{T}_{1a}$.

In polycrystalline singlet fission materials, the anisotropy of the $^1\text{T}_1\text{T}_1$ states may preserve within individual crystalline grains. The random orientation of those grain boundaries, however, is bound to suppress the global expression of the anisotropy. Very uniquely, our studies in the form of single crystals allow us to unravel the anisotropic nature of the $^1\text{T}_1\text{T}_1$ state without ambiguity. Previous studies of polycrystalline acenes and other singlet fission materials showed that the energy level of a triplet pair $^1\text{T}_1\text{T}_1$ is higher than that of a decoupled triplet dimer (Basel et al., 2019; Yong et al., 2017). Recently, a triplet pair $^1\text{T}_1\text{T}_1$ was reported to be bound relative to free triplets with an energy of $30\text{ meV}$, which is largely material independent (Yong et al., 2017). Our results not only demonstrated a higher energy of $^1\text{T}_1\text{T}_1$ than $\text{T}_1 + \text{T}_1$, but also exhibit their anisotropic features in hexacene.

### Anisotropic Quantum Decoherence of $^1\text{T}_1\text{T}_1$

The transition dipole strength for the triplet pair $^1\text{T}_1\text{T}_1$ state is generally too weak to be detected so that its quantum decoherence is usually assumed to be much faster than its formation (Berkelbach et al., 2014; Chan et al., 2013; Coto et al., 2015; Mirjani et al., 2014; Tamura et al., 2015; Yost et al., 2014). Nevertheless, some studies implied that the quantum decoherence rate of the $^1\text{T}_1\text{T}_1$ state could be as slow as its formation rate (Feng and Krylov, 2016; Kolomeisky et al., 2014; Monahan et al., 2017; Pensack et al., 2016). In the
present study, we found that $k_D$ is even slower than $k_F$ along the long $a$ axis, whereas $k_D$ along the short $b$ axis is comparable with $k_F$. Our results indicate that the relatively slow quantum decoherence is as important as triplet pair formation for the overall singlet fission rate in hexacene. According to the Redfield quantum dissipation theory (Ishizaki and Fleming, 2009), the quantum decoherence rate, $k_D$, due to system-bath coupling is given by:

$$k_D = \frac{2\lambda \omega_p \Delta E}{\Delta E^2 + \hbar^2 \omega_p^2} \left( \frac{\Delta E}{e^{k_B T}} \right)$$

(Equation 3)

where $\Delta E$ is the energy gap between the initial and final states of quantum decoherence, $\lambda$ is the corresponding reorganization energy, and $\omega_p$ is the system-bath coupling frequency. If the quantum decoherence of $^1\{T_1T_1\}$ pair in hexacene crystal is assumed to be driven by vibronic coupling only, $\omega_p$ can be ascertained by the functional mode analysis (Hub and de Groot, 2009), which projects the diabatic energy gaps between $^1\{T_1T_1\}$ and $T_1 + T_1$ onto the dimer’s vibrational normal modes for 5,000 snapshots extracted from our MD trajectory. It was found that the quantum decoherence is predominantly driven by a few slow vibrational modes with $\omega_p < 50$ cm$^{-1}$ (Figure S11). Thus, the quantum decoherence is mediated by the electron-phonon interaction in crystalline hexacene. Even if we account for the small contributions from other vibrational modes that are usually much faster, the calculated effective driving mode, $\omega_p = \left( \sum_{i=1}^{N_v} C_i^2 \omega_i \right)$, is still as slow as $\sim$40 cm$^{-1}$ (Table S3). Therefore, $\omega_p$ is an important factor for the quantum decoherence of $^1\{T_1T_1\}$ pair in hexacene because of its notable mismatch with $\Delta E$, i.e., $\hbar \omega_p \Delta E \rightarrow k_D \propto \omega_p \Delta E^{\lambda}$. Interestingly, the $\Delta E$ along $a$ axis is nearly two times as large as its counterpart along $b$ axis, resulting in a remarkable directional heterogeneity of $k_D$, i.e., $k_D^{a,b} \approx 1.7$. Besides the experimentally consistent heterogeneity factor, our calculated values of $k_D$ along the two crystal axes are also well in line with the results from our ultrafast spectroscopy studies (Table S2).

Previous studies of singlet fission in pentacene and hexacene were performed on their polycrystalline films (Bakulin et al., 2016; Busby et al., 2014; Chan et al., 2011; Kandada et al., 2014; Rao et al., 2011; Wilson et al., 2011, 2013). Fission rates of the films are, in general, the averaged result over different orientations of the polycrystalline structures, leading to a loss of intrinsically anisotropic features in these materials. Transient absorption microscopy experiments found that long-lived correlated triplet pairs exist and triplet interaction and binding could be induced by a $\pi$-staked geometry in crystalline pentacene derivative (Folie et al., 2018). Polarization measurements of tetracene demonstrated that there was no difference in kinetics along the long and short axes (Schwoerer and Birech, 2014; Wan et al., 2015; Zhang et al., 2014). By contrast, our results showed that the anisotropic quantum decoherence of $^1\{T_1T_1\}$ occurs in single crystalline hexacene. This decoherence process is driven by the vibronic coupling between the $^1\{T_1T_1\}$ state and some low-frequency phonon modes of hexacene crystal. Owing to the directional asymmetry of the crystal, this quantum decoherence process might be intrinsically anisotropic as governed by the energy gap between $^1\{T_1T_1\}$ and $T_1 + T_1$.

In summary, we discovered anisotropic singlet fission in single crystalline hexacene and have revealed its mechanism by deciphering its two constituent steps. For the first step that gives rise to correlated triplet pairs through the so-called direct mechanism, no anisotropy was found as they were formed on the same timescale of $\sim$200 fs along the two crystal axes. In the second step that involves quantum decoherence of the correlated triplet pairs, the rate along the short $b$ axis is nearly two times as fast as that along the long $a$ axis. The difference on the rate might be ascribed to the directional heterogeneity of the hexacene crystal that results in distinct thermdynamic stabilities between the initial and final states of the quantum decoherence, which is driven by system-bath coupling with a slow effective frequency of $\omega_p < 50$ cm$^{-1}$. Our findings not only corroborated the importance of quantum decoherence in fission process, but will also guide future experimental and theoretical endeavors of exploring anisotropic photophysical properties in novel materials for multiple exciton generation.

**Limitations of the Study**

From a fundamental point of view, one of the most challenging tasks for the singlet fission community is the characterization and monitoring of the optically dark $^1\{T_1T_1\}$ state due to its small absorption cross section and short lifetime upon photo-excitation. Although the transient absorption spectra of the $^1\{T_1T_1\}$ state were presented in recent experiments (Burdett and Bardeen, 2012; Korovina et al., 2016; Lukman et al.,
2015, 2016, Stern et al., 2015, 2017), those results are limited to intramolecular singlet fission or intermolecular one for dimers in solution (Rao and Friend, 2017) with unusually long \(^1{(T_1,T_1)}\) lifetime. Therefore, it is not surprising that the optical identification of the short-lived \(^1{(T_1,T_1)}\) state in hexacene has not been reported yet with the transient absorption spectroscopy method. More recently, the two-dimensional optical spectroscopy was employed to demonstrate the existence of \(^1{(T_1,T_1)}\) state in thin film pentacene and its derivatives (Bakulin et al., 2016). Nevertheless, this technique has to be coupled with a microscopy approach for small-size samples such as single crystalline hexacene, our system of interest.

METHODS

All methods can be found in the accompanying Transparent Methods supplemental file.

SUPPLEMENTAL INFORMATION

Supplemental Information can be found online at https://doi.org/10.1016/j.isci.2019.08.053.

ACKNOWLEDGMENTS

This work was supported by the Honda Research Institute (Ohio) before June 1, 2015, by Air Force Office of Scientific Research (AFOSR) (FA9550-15-1-0213) between June 1, 2015, and July 31, 2017, and by Utah State University after August 1, 2017. D.S. was supported by the W. M. Keck Foundation. Computational resources were provided by the Argonne Leadership Computing Facilities at Argonne National Laboratory under Department of Energy contract DE-AC-06CH11357 and by the Extreme Science and Engineering Discovery Environment at Texas Advanced Computing Center under National Science Foundation contract TG-CHE130008. Y.R. thank Drs. Tony F. Heinz, Omer Yaffe, Xiaoyang Zhu, and Francis Spano for their beneficial discussion.

AUTHOR CONTRIBUTIONS

D.S., G.-H.D., B.X., Y.W., and Y.Q. performed the transient absorption measurements and characterizations. E.X. performed the theoretical calculation. X.L. and Y.Z. prepared the samples. D.S., G.-H.D., B.X., C.N., A.R.H., H.-L.D., G.C., H.C., and Y.R. analyzed the data. Y.R., G.C., A.R.H., C.N., and H.-L.D. designed the project. Y.R., G.C., C.N., A.R.H., and H.-L.D. supervised the experiments. H.C. supervised the theoretical calculation. D.S, G.-H.D, B.X., and E.X. wrote the original draft. Y.R., H.C., and G.C. revised the manuscript.

DECLARATION OF INTERESTS

**Transparent Methods**

*Preparation of Single Crystals*

Hexacene single crystals were grown in a physical vapor transport (PVT) furnace at atmospheric pressure. Hexacene precursor was synthesized according to a previously reported method (Laudise et al., 1998; Watanabe et al., 2012). ~1 mg hexacene powder was heated in a hot zone of the furnace at 300 °C for a week. 50 SCCM of ultrahigh purity argon gas (99.999%) was used as purging gas as well as carrier gas. Hexacene single crystals were collected in the crystallization zone. Single crystals grown in this manner were first spread on a quartz substrate. The hexacene crystal face for this method tends to grow parallel to the substrate, namely (001). A gasket sealed container to hold the quartz substrate was assembled in the N₂ box to protect the single crystals from oxygen during optical experiments.

*Experimental Setup for Micro Transmission UV-vis Spectrometer*

The optical absorption measurements of hexacene single crystals were performed on a home-built microscope equipped with a lamp (Lumina-I) as an unpolarized broadband radiation source. Briefly, an intensity-tunable halogen-lamp and a LED pen light were used as the UV-vis light source for the UV-vis transmission measurements and the illumination light for the microscope, respectively. A beam splitter combined both the UV-vis and illumination light for a collinear light path. An objective with 10× magnification subsequently focused the selected polarized light onto a hexacene single crystal at normal incident angle. A condenser was used to collect the transmitted light that is turn was focused into a grating spectrometer (Andor Shamrock 500 with a grating blazed at 500nm, 150 groove/mm), followed by a thermo-cooled CCD (Andor Newton). A polarizer was placed between the lamp and the objective to select the polarization of the incident light. Only a few of crystallites met the requirements of the optical measurements on each substrate, even though small single crystals have been intentionally prepared. The thicknesses of the chosen hexacene samples were estimated to be on the order of ca. 0.5 μm according to the absorption coefficient of hexacene thin films reported in the literature. All experiments were performed at room temperature.

*Micro-transient Absorption Spectrometer*
A home-built microscope was coupled with a transient absorption setup for our micro-
 transient absorption measurements (Figure S1). We used 1 KHz regeneratively amplified Ti:
 Sapphire laser system to generate laser pulse with a center wavelength at 795 nm. The pulse
duration is about 100 fs. The laser pulse was then split into two parts: one part was coupled
with a motorized delay stage (Klinger) as a pump light, and the other part was focused onto
a sapphire crystal plate to generate white light super-continuum as a probe light. Both the
pump light and the probe light have been combined by a pellicle beam splitter and sent to
the objective. Two more beam splitters were used along the beam path to couple the
illumination light and a CMOS camera for imaging samples. The transmitted probe light
was collected by a condenser and sent to the spectrometer and CCD (Andor Shamrock and
Andor Newton, respectively). The pump light was blocked after passing the samples by
placing an appropriate band pass filter. The time-dependent changes in absorption spectra
have been obtained by switching on/off of the pump pulse. The CCD sampling rate of 200
Hz was synchronized with an optical chopper. A detection sensitivity of about $5 \times 10^{-4}$ was
achieved.

**Estimation of Photo-excited Carrier Density for Singlet Fission**

We estimated the photo-excited carrier density as follows:

1). We measured the transmission of the hexacene sample on quartz comparing with clean
quartz substrate and observed approximately 20-fold decrease of the transmission light at
730 nm. By using a known extinction coefficient for hexacene single crystal at the same
wavelength ($0.25 \times 10^5$ cm$^{-1}$), we obtained the crystal thickness of about 520 nm.

$$I(z) = I(0) \cdot 10^{-\alpha(\lambda)z}$$

$$z = \log_{10}(\frac{20}{\alpha(\lambda)}) = 520\text{nm}$$

2). For 0.25 μW 795 nm femtosecond laser pulse, the number of photons per volume is
given by
If we assume that each absorbed photon generates one singlet exciton, the initial singlet exciton density is $2.1 \times 10^{19} \text{ cm}^{-3}$.

4). Laser fluence:

$$\frac{\text{Energy / pulse}}{\text{area}} = \frac{0.25 \text{nJ} / (7/3)}{\pi \times (4.5 \mu\text{m})^2} = 170 \mu\text{J} / \text{cm}^2$$

5). Excitation volume:

$$V_{\text{ext}} = \text{Area} \times \text{Thickness} = \pi \times (4.5 \mu\text{m})^2 \times 0.52 \mu\text{m} = 33 \mu\text{J} / \text{cm}^2$$

6). Volume of hexacene:

$$a = 7.673 \text{Å}, b = 6.292 \text{Å}, c = 16.242 \text{Å}$$

$$V = abc = 784.13 \text{ Å}^3$$

Since there are two molecules in a unit cell, the volume of each molecule is $392.06 \text{ Å}^3$.

7). The ratio of excited molecule density vs total molecule density:

$$\frac{D_{\text{ext}}}{D_{\text{tot}}} = \frac{2.1 \times 10^{19} \text{ cm}^{-3}}{1 / 392 \text{ Å}^3} = 8.5 \times 10^{-3}$$

8). The expected pump probe signal without considering singlet fission:

$$\frac{\Delta T}{T} (S_0 - S_1) = \sigma(S_0) \times N(S_1) = 1.1 \times 10^{-2}$$

**Coupled Rate Equations of Singlet Fission**

$$S_0 + S_1 \xrightarrow{k_F} \left( T_1 T_1 \right) \xrightarrow{k_F} T_1 + T_1$$

$k_F$: the formation rate of a correlated triplet pair state
By solving the two-step coupled rate equation, we can write the population dynamics for singlet and triplet exciton as

\[
\text{Singlet}(t) = A_0 e^{-k_it}
\]

\[
TT(t) = \frac{k_F A_0}{k_F - k_Q} \left( e^{-k_F t} - e^{-k_Q t} \right)
\]

\[
T_1(t) = A_0 \left( 1 + \frac{1}{k_F - k_Q} \left( k_Q e^{-k_Q t} - k_F e^{-k_F t} \right) \right)
\]

Equation S1

**Global Fitting Based on Coupled Rate Equations for Singlet Fission**

We noticed that all the kinetic traces include both the contributions from the \(S_1 \rightarrow S_n\) and \(T_1 \rightarrow T_n\) transitions. As such, we made our kinetic analyses by considering: 1) Transient responses at any energy are a sum of the \(S_1 \rightarrow S_n\) and \(T_1 \rightarrow T_n\) transitions; 2) Singlet fission is a two-step process with two independent rates, namely \(k_F\) and \(k_Q\). The justification of the latter was based on the fact that the decay rate of \(S_1\) is not consistent with the generation rate of \(T_1\) from our kinetic data, in particular along the \(a\) axis. Specifically, we treat \(\Delta T/T(E, t)\) as a sum of the contributions from both the \(S_1\)-\(S_n\) and \(T_1\)-\(T_n\) transitions at a given energy:

\[-\Delta T/T(E, t) = \sigma_{S1-Sn}(E)n_{S1}(t) + \sigma_{T1-Tn}(E)n_{T1}(t),\]

where \(n_{S1}(t)\) and \(n_{T1}(t)\) are standard time-dependent populations of a two-step sequential reaction as given in Equation 1, and \(\sigma_{S1-Sn}(E)\) and \(\sigma_{T1-Tn}(E)\) are the cross sections for the \(S_1 \rightarrow S_n\) and \(T_1 \rightarrow T_n\) transitions.

Based on the kinetic model and the rate equations described above, we are able to apply the global fitting to our transient absorption data at different time delays. The change in measured transient transmission is proportional to the absorption cross section for each of the three following transitions: \(S_0 \rightarrow S_1\), \(S_1 \rightarrow S_n\) and \(T_1 \rightarrow T_n\).
Since the time-dependent spectra for the three transitions are highly overlapped, we treated every spectral region as a mixture of singlet and triplet excitons. Therefore, it takes the form as:

\[
\frac{\Delta T}{T}(E, t) = (\sigma_{S_0}(E, t) - \sigma_{S_1}(E, t))N_{S_1}(t) + (\sigma_{S_0}(E, t) - \sigma_{T_1}(E, t))N_{T_1}(t)
\]

In light of the excitation pulse temporal profile, we used the following fitting function for our data:

\[
\frac{\Delta T}{T} = \text{Erf}(c1 \times (t-c2)) \times \frac{1}{2} + c3 \times e^{-k_p t} + c4 \times \left(1 + \frac{1}{k_F - k_Q} (k_Q e^{-k_Q t} - k_F e^{-k_F t})\right)
\]

where Erf denotes the Gauss error function.

**Triplet Davydov Splitting of Pentacene Single Crystals**

We performed polarized transient absorption experiments on pentacene single crystals too. Figure S5 shows transient absorption spectra of pentacene single crystals at a time delay of 4 ps with probes along the long \(a\)-axis and the short \(b\)-axis when a 400-nm photoexcitation is applied along the \(b\)-axis. The \(T_1 \rightarrow T_n\) transitions exhibit different absorption peaks at 608 nm and 618 nm along the long \(a\)-axis and short \(b\)-axis, respectively. The triplet Davydov splitting results show that the triplet energy level along the \(b\)-axis is higher than that along the \(a\)-axis, i.e., \(E_{T_{1b} + T_{1b}} > E_{T_{1a} + T_{1a}}\).
Technical Details of Quantum Mechanics/Molecular Mechanics Simulations

In our hybrid quantum mechanics/molecular mechanics (QM/MM) study, density functional theory (DFT) (Hohenberg et al., 1964) was employed to accurately model the singlet fission process within a hexacene tetramer, which was selected to span along the $a$ and $b$ crystal axes. In addition, all nearest-neighboring molecules of the tetramer were also included in the QM subsystem to account for the electronic polarization effect. By contrast, generalized AMBER empirical force field (GAFF) (Wang et al., 2004) was used to efficiently describe the thermal fluctuation of other hexacene molecules consisting of the MM subsystem. Unless other specified, all QM/MM simulations were performed using CP2K package (VandeVondele et al., 2005) with Goedecker-Teter-Hutter (GTH) pseudopotential, (Goedecker et al., 1996) optimally tuned range-separated hybrid Perdew-Burke-Ernzerhof ($\omega$-RSH-PBE) exchange-correlation functional, (Jacquemin et al., 2014) polarized-valence-double-$\zeta$ (PVDZ) basis set, (Woon et al., 1994) electrostatic QM/MM coupling scheme, (Laino et al., 2005) and a wavelet-based Poisson solver. (Genovese et al., 2006)

Simulated Formation Rate of Correlated Triplet Pair

As shown in Table S1, the optical gap for the $S_0S_0 \rightarrow S_0S_1^*$ transition along $a$ axis is 1.65 eV, which is 0.23 eV higher than its counterpart along $b$ axis. In spite of their relatively small difference on the optical gap, these two optical transitions have distinct oscillator strengths, i.e., $5.57 \times 10^{-3}$ vs. $8.94 \times 10^{-3}$, making the light absorption along $b$ axis nearly 60% stronger than that along $a$ axis. Both of our calculated optical gaps and oscillator strengths are well in line with the experimental absorption spectrum (Figure. 1C).
In our FMSF theory (Elenewski et al., 2017b), the effective vibrational mode that drives singlet fission, is a linear combination of all normal modes, \( V_{SF} = \sum_i c_i \vec{V}_i \), where \( c_i \) reflects the relative importance of the \( i \) th normal mode. Mathematically, \( \{c_i\} \) can be ascertained by maximizing the Pearson’s correlation coefficient between \( \{\vec{V}_i\} \) and \( \{\Delta E_i^d\} \) (Chen, 2014) where \( \Delta E_i^d = E_{S_0S_1^*} - E_{TT} \) is the energy gap between \( S_0S_1^* \) and \( (TT) \). Specifically, our training set for \( V_{SF} \) consists of 3,000 snapshots extracted from a 3-ns trajectory of molecular dynamics (MD) simulation. As shown in Figure S8, regardless of the lattice direction of singlet fission, \( V_{SF} \) is always a ring-stretching mode that is collectively exerted by two adjacent hexacene molecules. Therefore, it is not surprising that the profile of \( c_i^2 \) features a few prominent peaks around 1200 cm\(^{-1}\) and 1500 cm\(^{-1}\), making the vibrational quantum tunneling effect important for singlet fission since \( \hbar \omega_{\text{vib}} \gg k_B T \). As a prudent measure to ensure the statistical quality of \( V_{SF} \), the determined \( c_i^2 \) were projected onto another 3000 snapshots extracted from a different MD trajectory for cross validation. It turns out that the cross-validated Pearson’s coefficients, \( R_{aa}^C = 0.88 \) and \( R_{bb}^C = 0.88 \), are only slightly smaller than their counterparts of the training set \( R_{aa} = 0.92 \) and \( R_{bb} = 0.91 \) (Figure S9), suggesting satisfactory sampling for the functional mode analysis of \( V_{SF} \).

Once the composition of \( V_{SF} \) is ascertained, we can evaluate its effective angular frequency \( \Omega = \sqrt{\frac{\hbar}{\Delta E}} \sum_i c_i^2 \omega_i \) by assuming that the contribution of a given normal mode to
λ is proportional to its relative importance to \( \vec{V}_{SF} \). As listed in Table S2, \( \lambda \) along \( a \) axis is 0.46 eV, which is 0.06 eV higher than that along \( b \) axis. The moderate difference on \( \lambda \) can be ascribed to a greater distortion of the hexacene crystal needed to accommodate a longer spin separation distance along \( a \) axis. Nevertheless, \( \Omega_{\omega a} \) of 1752 cm\(^{-1}\) is even slightly slower than \( \Omega_{\omega b} \) of 1902 cm\(^{-1}\) due to the higher weights of slower vibrational modes in \( \vec{V}_{SF} \) along \( a \) axis (Figure S8). Interestingly, the values of both \( \lambda \) are less than \( |\Delta G_0| \), placing the singlet fission into the inverted Marcus region. The applicability of Marcus-type non-adiabatic transition theory is further justified by our calculated feeble electronic coupling strengths of \(~10\) meV, which are in line with previous studies on other acenes. (Elenewski et al., 2017a; Yost et al., 2014)

Besides singlet fission, another important decay channel for an optically populated \( S_0S_1^* \) vibronic state is its thermal relaxation. According to the phonon scattering theory, (Li et al., 2014) the lifetime of a given vibrational normal mode, \( \vec{V}_i \), is decided by its anharmonic coupling with others. If only the third-order anharmonicity is considered, its decay rate, \( \Gamma_i \), is given by:

\[
\Gamma_i = \sum_j \sum_k \frac{\hbar \pi (f_i + f_k + 1)}{4 \omega_i \omega_j \omega_k} \left| \frac{\partial^3 E}{\partial \vec{V}_i \partial \vec{V}_j \partial \vec{V}_k} \right|^2 \delta (\omega_i - \omega_j - \omega_k)
\]

Equation S4

where \( \omega \) s are the angular frequencies, \( f = \frac{1}{e^{\hbar \omega / k_B T} - 1} \) is the Bose-Einstein distribution function, \( \frac{\partial^3 E}{\partial \vec{V}_i \partial \vec{V}_j \partial \vec{V}_k} \) is the third-order derivate of energy with respect to all participating
normal modes, and δ is the Dirac delta function. Using the ALAMODE simulation package (Tadano et al., 2014) the third-order anharmonicity of our system was evaluated through a non-linear least squares regression subject to translational symmetry constraint. Thereafter, \( \Gamma_i \) was calculated by exploring all energy-conversing scattering events. The profile of \( \Gamma_i \) weighted by \( c_i^2 \) (Figure S10) again features a couple of distinct peaks at \( \sim 1200 \text{ cm}^{-1} \) and \( \sim 1500 \text{ cm}^{-1} \), further signifying the importance of these ring-stretching normal modes not only to singlet fission but also to thermal relaxation. Now, with all needed parameters in hand, we can apply Eq.2 to calculate \( k_F \) under non-thermalized condition. It was found that \( k_F^{aa} \) of 0.93 ps\(^{-1}\) is nearly same as \( k_F^{bb} \) of 0.83 ps\(^{-1}\), in spite of a modest disparity in energetic parameters such as \( \Delta G_0 \) and \( \lambda \). The diminished difference on \( k_F \) along \( a \) and \( b \) axes primarily arises from their fast \( \Omega \)'s, whose zero-point energies become much more overwhelming for vibrational quantum tunneling. If the fluorescent decay of \( S_0S_1^* \) to \( S_0S_0 \) is negligible, the overall decay rate, \( k_D \), of \( S_0S_1^* \) is simply \( k_F + \Gamma \), leading to \( k_D^{aa} \) of 1.86 ps\(^{-1}\) and \( k_D^{bb} \) of 2.08 ps\(^{-1}\).

Derivation of Energy Gap Associated with Quantum Decoherence

Using a two-electron-two-orbital scheme, one can easily construct the three constituent states for a molecule at its triplet state:
where we denote the upper and lower orbitals as $a$ and $b$, respectively. Similarly, we can construct another molecule’s triplet state using different upper and lower orbitals denoted as $c$ and $d$:

$$T_y = \frac{1}{\sqrt{2}} \left( \begin{array}{c} \uparrow \\ \uparrow + \downarrow \end{array} \right)$$

Equation S6

For a fully decoupled $T_x + T_y$ dimer, all nine possible cross-molecule combinations of the constituent states are equally weighted, resulting in an energy expectation value of

$$E_{r_x+r_y} = -k_b T \ln(3 \times 3) + E_{coulomb} + E_{x}^{ab} + E_{x}^{cd} + \frac{1}{2} (E_{x}^{ac} + E_{x}^{bc} + E_{x}^{ad} + E_{x}^{bd})$$

Equation S7

where $k_b \ln(3 \times 3)$ is the electronic entropy, $T$ is the temperature, $E_{coulomb}$ is the coulomb energy arising from all orbital pairs, and $E_{x}$ stands for the exchange energy between a selected orbital pair. For example, $E_{x}^{ab}$ is the exchange energy between orbital $a$ and orbital $b$. 
Alternatively, $E_{T_x+T_y}$ can be expressed as

$$E_{T_x+T_y} = -k_b T \ln 9 + \frac{3}{2} E_{HS} - \frac{1}{2} E_{LS}$$

Equation S8

where $E_{HS}$ and $E_{LS}$ are the energies of the following spin configurations:

$$\begin{pmatrix} \uparrow & \uparrow \\ \downarrow & \downarrow \end{pmatrix} \text{ and } \begin{pmatrix} \uparrow & \downarrow \\ \downarrow & \uparrow \end{pmatrix}$$

respectively.

For a $\begin{pmatrix} T_x \ T_y \end{pmatrix}$ pair at its singlet state:

$$\begin{pmatrix} T_x \ T_y \end{pmatrix} = \frac{1}{\sqrt{3}} \left( \begin{pmatrix} \uparrow & \downarrow + \downarrow & \uparrow \end{pmatrix} - \frac{1}{2 \sqrt{3}} \left( \begin{pmatrix} \uparrow & \uparrow + \uparrow & \uparrow + \downarrow & \uparrow + \downarrow & \uparrow + \downarrow \end{pmatrix} \right) \right)$$

Equation S9

its energy is given by:

$$E_{\begin{pmatrix} T_x \ T_y \end{pmatrix}} = k_b T \ln(9) + E_{\text{coulomb}} + E_{ab} + E^{cd} - \frac{1}{2} \left( E_{ac} + E_{bc} + E_{ad} + E_{bd} \right)$$

Equation S10

which can be further simplified as

$$E_{\begin{pmatrix} T_x \ T_y \end{pmatrix}} = \frac{1}{2} E_{HS} + \frac{1}{2} E_{LS}$$

Equation S11

Through a comparison between Eq. 4 and Eq. 7, we found that

$$\Delta E_{QD} = E_{\begin{pmatrix} T_x \ T_y \end{pmatrix}} - E_{T_x+T_y} = k_b T \ln 9 + E_{LS} - E_{HS} = k_b T \ln 9 + E_{HS \rightarrow LS}$$

Equation S12
where $E_{HS \rightarrow LS}$ is the associated spin-flip energy.
