ABSTRACT

We report here on the discovery with XMM-Newton of pulsations at 22 ms from the central compact source associated with IKT 16, a supernova remnant in the Small Magellanic Cloud (SMC). The measured spin period and spin period derivative correspond to 21.7661076(2) ms and 2.9(3) × 10−14 s s−1, respectively. Assuming standard spin-down by magnetic dipole radiation, the spin-down power corresponds to 1.1 × 1038 erg s−1 implying a Crab-like pulsar. This makes it the most energetic pulsar discovered in the SMC so far and a close analogue of PSR J0537–6910, a Crab-like pulsar in the Large Magellanic Cloud. The characteristic age of the pulsar is 12 kyr. Having for the first time a period measure for this source, we also searched for the signal in archival data collected in radio with the Parkes telescope and in γ-rays with the Fermi/LAT, but no evidence for pulsation was found in these energy bands.

Key words: ISM: individual objects: IKT 16 – ISM: supernova remnants – Radio continuum: ISM – Radiation mechanisms: general – Magellanic Clouds

1 INTRODUCTION

The Large and the Small Magellanic Clouds (LMC and SMC) are gas-rich irregular galaxies orbiting the Milky Way. The relatively close distance of ~60 kpc to the SMC and low Galactic foreground absorption (NH ~ 6 × 1020 cm−2) enable the study of its entire X-ray source population down to a luminosity of ~1033 erg s−1 (Sturm et al. 2013). The recent star formation activity (~40 Myr ago), has created an environment where a large number of massive stars are expected, many of which are companions in high mass X-ray binary (HMXB) systems (Harris & Zaritsky 2004). In tune with this, a large population of HMXBs (predominantly Be X-ray binaries) has been discovered and extensively studied in the SMC. Pulsations have been detected in 63 of these systems, confirming their nature as neutron stars. These Be X-ray binary pulsars are typically a few 10 million years old and have spin periods ranging from 1 to 2000 s (Haberl & Sturm 2016). On the other hand, of the ‘younger’ population of isolated neutron stars that constitute the rotation powered pulsars, just a handful in number are known. Only seven such systems have been discovered in the SMC until now from radio surveys (Crawford et al. 2001; McConnell et al. 1991; Manchester et al. 2006; Titus et al. 2019) and their detection may be prone to several selection effects and observational biases (see for e.g. Titus et al. 2020).

Ideal sites to search for young rotation powered pulsars are supernova remnant (SNR) – pulsar wind nebula (PWN) composites; Composite SNRs are robust indicators of the presence of a young and energetic pulsar powering the PWN by an outflow of relativistic particles that interact with its natal SNR and the surrounding interstellar medium. Only two such systems are known in the SMC at this date, namely DEM 55 and IKT 16 (Alsaber et al. 2019; Maitra et al. 2015). IKT 16 is a large X-ray and radio-faint SNR, in which a central source of hard X-ray emission was identified using XMM-Newton (van der Heyden et al. 2004). In a detailed analysis using additional XMM-Newton observations, Owen et al. (2011) found substantial evidence that the unresolved point source detected at the center of the SNR is a PWN associated with it. Follow-up observations with Chandra resulted in resolving the PWN at the centre of IKT 16, the first such conclusive evidence in the SMC (Maitra et al. 2015). The putative neutron star at the centre of the PWN could be seen as a point source using Chandra and was ~3 times brighter than the soft, symmetric nebula surrounding it. This pointed to the

2 C. Maitra et al.

presence of an energetic pulsar dominated by non-thermal emission. We report here the discovery of pulsations from the central source in IKT 16 (PSR J0058–7218 from now), confirming its nature as an energetic rotation powered pulsar. Sect. 2 presents the X-ray observations and analysis, Sect. 3 the search for counterparts in the radio and y-ray wavebands, and the discussion and the conclusions follow in Sect. 4.

2 OBSERVATION AND ANALYSIS

IKT 16 was observed with the European Photon Imaging Camera (EPIC) on board the XMM-Newton satellite starting on 2020 March 15 for an orbit (Obsid 0841450101). The EPIC-pn (Struder et al. 2001) was set in small window mode (timing resolution of 5.6718 ms), while both MOS detectors (Turner et al. 2001) were operating in full frame mode (timing resolution of 2.6 s). All instruments mounted the medium optical-blocking filter. The raw data were analyzed with the XMMASAS v.18.0 software package. We searched for periods of high background flaring activity by extracting light curves in the energy range of 7.0–15.0 keV and removed the time intervals with background rates $\geq 8$ and 2.5 counts s$^{-1}$ arcmin$^{-2}$ for EPIC-pn and EPIC-MOS, respectively. Finally, the net exposure times for pn, MOS1, MOS2 are 117.8, 124.4 and 125.9 ks respectively not considering for instrument time. The source counts were selected from a circular region with radius of 20 arcsec. For the EPIC-pn camera, the background spectra were accumulated in nearby regions in the same CCD as the source, avoiding as much as possible the SNR. The total source and background counts for the PN camera are 6546 and 3868 respectively. In case of the EPIC-MOS cameras, which were in full-frame mode, background regions were extracted taking into account the SNR centre and size as measured in Owen et al. (2011), so to avoid the SNR emission.

2.1 X-ray timing analysis

To search for a periodic signal, we started with the barycentre-corrected XMM-Newton EPIC-pn data (owing to their better time resolution with respect to the MOS data) in the energy range of 0.4–10.0 keV by using a Lomb–Scargle periodogram analysis$^1$ in the period range of 12 ms to 1 s (Lomb 1976; Scargle 1982). A strong periodic signal is detected around 22 ms (Fig. 1). We also verified the result by producing a power density spectra and found a strong peak at the same frequency. The Fourier power with Leahy normalization (Leahy et al. 1983) corresponded to 592.7 which leads to a chance probability of $3 \times 10^{-122}$ considering 1677216 trial frequencies searched. A similar exercise performed by extracting events from a large background region did not produce the same peak, thus firmly establishing its origin from the source.

In order to determine the period more precisely, we employed the Bayesian periodic signal detection method described by Gregory & Loredo (1996). The spin period and its associated 1σ error are determined to be $1.0 \times 10^{-13}$ (without taking into account a period derivative) indicating the spin period of the neutron star in the centre of IKT 16.

To check for a period derivative, we divided the exposure in 9 segments and performed a phase-fitting analysis (see e.g. Phinney 1992). A constant period (a first-order polynomial function)

\[ P = \frac{1}{2} P_0 + \frac{1}{2} \left( P_0 - \frac{1}{2} P_0 \right) \]

is clearly incompatible with the data, with a reduced $\chi^2 (\chi^2_{\text{red}}) = 12.85$ for 7 degrees of freedom (df). The introduction of a period derivative (a second-order polynomial) yields an acceptable fit ($\chi^2_{\text{red}} = 1.26$ for 6 df). The best-fitting period derivative is $P = 2.9(3) \times 10^{-14} \text{s}^{-1}$. We give the complete phase-coherent spin ephemeris and the derived pulsar properties in Table 1, and in Fig. 2 we show the epoch folded pulse profiles in different energy bands. The pulse profiles are single peaked in all energy bands and do not show any apparent energy dependence. The pulsed fraction, defined as $(M - m)/(M + m)$, where $M$ is the maximum of the pulse profile and $m$ the minimum, is $(73 \pm 3)\%$, $(68 \pm 5)\%$ and $(79 \pm 5)\%$ in the 0.4–10 keV, 0.4–1.5 keV and 1.5–10 keV energy bands, respectively. As explained in the next session, the pulsar X-ray emission is contaminated, mainly in the soft energy band, by its PWN and by the surrounding SNR and, therefore, these values should be interpreted as lower limits to the pulsar intrinsic pulsed fraction.

### Table 1.

| Parameter                  | Value                        |
|----------------------------|------------------------------|
| Range (MJD)                | 58924.016–58925.583          |
| Epoch (MJD)                | 58924.0                      |
| Frequency, $\nu$ (Hz)      | 45.9429870(4)               |
| Frequency derivative, $\dot{\nu}$ (Hz s$^{-1}$) | -6.1(6) x 10$^{-11}$ |
| Period, $P$ (ms)           | 21.7661076(2)               |
| Period derivative, $\dot{P}$ (s$^{-1}$) | 2.9(3) x 10$^{-14}$ |
| Characteristic age, $\tau_c$ (kyr) | 12                       |

safely subtracted from the pulsar XMM-Newton spectrum selecting a nearby background region. However, since the SNR spectrum is rather different from that of the central point source, we defined a background region away from the SNR shock boundary as defined in Owen et al. (2011), and modelled the central source and the SNR emission components in IKT 16 simultaneously in the spectral fit. Since the EPIC-pn was operated in small window mode, such a background region could be properly defined away from the SNR region only for the MOS cameras. On the other hand, the time resolution of the pn data and the discovery of pulsations allow us to analyse, for the first time, the spectrum of the pulsed emission. In this case, the contribution from both the contaminating sources can be completely eliminated by subtracting the off-pulse emission from the on-pulse spectrum extracted from the same region. The corresponding phase intervals are indicated in Fig. 2.

For the spectral analysis, the XMMSAS tasks rafgen and arfgen were used to create the redistribution matrices and ancillary files. Spectra were binned to achieve a minimum of 25 counts per spectral bin. The spectral analysis was performed using the XSPEC fitting package (Arnaud 1996). The X-ray absorption was modeled using the tbabs model (Wilms et al. 2000) with atomic cross sections adopted from Verner et al. (1996). We used two absorption components: the first one describes the Galactic foreground absorption, where we used a fixed column density of $6 \times 10^{20}$ cm$^{-2}$ (Dickey & Lockman 1990) with abundances taken from Wilms et al. (2000). The second component accounts for the unknown SMC material in front of the object. For the latter absorption component, the abundances were set to SMC abundances (20% of the solar abundances). We adopted a power-law model to account for the emission from the pulsar. In the MOS phase-averaged spectrum, we included a Sedov component ($\text{vsedov}$) to model the SNR emission. The derived $N_H$ and SNR parameters are consistent with those obtained in Owen et al. (2011). The power-law index is $\Gamma \sim 1.4$ both in the total and in the pulsed spectrum. Since the PWN emission has a softer spectrum (Maitra et al. 2015), this indicates that, although it cannot be spatially resolved using XMM-Newton, its contribution to the total spectrum is marginal. The unabsorbed phase-averaged luminosity of PSR J0058–7218 in the 0.2–12 keV band is $10^{35}$ erg s$^{-1}$ (see Table 2). The best-fit parameters of the total and pulsed spectra of PSR J0058–7218 and the errors corresponding to the 90% confidence range are tabulated in Table 2.

3 SEARCH FOR RADIO AND $\gamma$-RAY COUNTERPART SOURCES

3.1 Search for a radio counterpart

A 4.5-hour long observation pointing at RA = 00$^h$58$^m$06$^s$931, Decl. = $-72^\circ19'17''616$, ~2.1 arcmin from the pulsar, was taken with the Parkes telescope on 2017 August 28 under the project P944 (Titus et al. 2019). The data were recorded at a central frequency of 1382 MHz with a bandwidth of 400 MHz and 1024 frequency channels. The sampling time is 64 $\mu$s and only the total intensity was recorded with 2-bit sampling. According to the free electron density model YNW16 (Yao et al. 2017), the dispersion measure (DM) towards the source is expected to be of the order of $140$ pc cm$^{-3}$. Another estimate for DM can be derived by the X-ray absorption column density, $N_H$, assuming an ionization fraction. In the Milky
Table 2. Best-fit parameters of the phase-averaged (EPIC MOS) and pulsed (EPIC pn) X-ray spectrum of PSR J0058—7218. The line-of-sight Galactic absorption was fixed to 6 × 10^20 cm\(^{-2}\) and the average spectrum was fitted simultaneously with the SNR emission. Errors are quoted at 90% confidence.

| Parameter                  | Total emission | Pulsed emission\(^b\) |
|----------------------------|----------------|-----------------------|
| \(N_\text{H}^{\text{total}}\) (10^{21} cm\(^{-2}\)) | 4 ± 2          | 6 ± 2                 |

| \(\chi^2\)                  | 100            | 177                   |
| Degrees of Freedom          | 111            | 156                   |

*Unabsorbed luminosity in the energy band of 0.2–12 keV, assuming a distance of 60 kpc. *Pulsed flux is evaluated with respect to 40% of the duty cycle, see Fig. 2.

Way, the average ionization is ~10%, as determined empirically from X-ray and radio measurements (He et al. 2013). The relation is not calibrated for the Magellanic Clouds, but if we assume 10%, the expected DM is consistently ~150 pc cm\(^{-3}\).

We performed a first targeted search by folding the Parkes data with the position and spin parameters obtained from the X-ray observation. The D$^2$PSR software package (van Straten &Bailes 2011) was used to fold the data with a sub-integration length of 10 s. The PDMP tool as a part of the PSRCHIVe software package (Hotan et al. 2004) was then used to search through a range of barycentric period and DM (0 to 1000 pc cm\(^{-3}\)) to find values giving the highest signal-to-noise ratio for potential pulsar signals. We also carried out a blind search, but no periodic signal was found over a DM range of 0 to 500 pc cm\(^{-3}\) using the PRESto software package\(^2\) (Ransom 2001; Ransom et al. 2002). No obvious detection was found in these searches, down to the data set sensitivity of 15 \(\mu\)Jy as calculated using the modified radiometer formula for pulsars (Lorimer & Kramer 2004). We also performed a search for single radio pulses using the Python-based pipeline named SPAR-D\(^3\) from Gajjar et al. (2018). Data were first processed through rfifind from the PRESto package for high-level radio frequency interferences purging. The pipeline is based on Heimdall (Barsdell et al. 2012) as its main kernel and we used it to search across a DM range from 0 to 1000 pc cm\(^{-3}\). The de-dispersed time-series were searched for pulses using a matched-filtering technique with a minimum window size equaling our time resolution (64 \(\mu\)s) and a maximum window size of 65 ms. The pipeline produced around 10 candidates at different DMs. Each candidate found by Heimdall was scrutinized to identify possible bursts but none were found down to a limiting fluence of 160 \(\mu\)Jy ms.

3.2 Search for a \(\gamma\)-ray counterpart

A young pulsar with such a large \(\dot{E}\) is expected to emit strongly in \(\gamma\) rays and could be visible for \textit{Fermi}-LAT, if the viewing angle is favourable. For example, PSR J0540–6919 in the Large Magellanic Cloud is easily detected at 2.8 ± 0.2 × 10^{-11} erg cm\(^{-2}\) s\(^{-1}\) (0.1–100 GeV). We have looked for a possible \(\gamma\)-ray counterpart in the 4FGL-DR2 catalogue (Abdollahi et al. 2020; Ballet et al. 2020). A faint source (4FGL J0509.7–7210 at 1.6 ± 0.4 × 10^{-12} erg cm\(^{-2}\) s\(^{-1}\)) is present 0.18° away from the pulsar’s position. The pulsar is just outside the 95% error ellipse of the LAT source, so it could be the counterpart. However, the 4FGL-DR2 catalogue lists the brightest star-forming region in the SMC (NGC346) as a plausible counterpart. It is closer to the LAT source than the pulsar, so we view the LAT flux as an upper limit to the pulsar’s \(\gamma\)-ray flux. The \(\gamma\)-ray spectral shape (curved, peaking just below 1 GeV) can be explained by either a pulsar or a star-forming region.

The LAT photons were folded at the frequency and frequency derivative obtained from the XMM-Newton observation, taking the source position from \textit{Chandra}, and no \(\gamma\)-ray pulsation was seen (D. Smith, private communication). Such a negative result does not make it possible to place a constraining upper limit to the pulsed flux, however, because the LAT source (if it is the pulsar) detects only ~40 photons per year, and maintaining phase coherence over 10 years for a young pulsar requires a more complex ephemeris.

4 DISCUSSION AND CONCLUSIONS

We report the discovery of a young and energetic pulsar PSR J0058–7218 inside the SNR IKT 16 in the SMC. X-ray pulsations are detected corresponding to a period of 21.7661076(2) ms. The pulsar spins down at a rate of 2.9(3) × 10^{-14} s\(^{-1}\) consistent with the scenario expected from a young rotation powered pulsar. Neither radio nor \(\gamma\)-ray pulsations are detected from the existing archival observations using the Parkes and \textit{Fermi}/LAT data respectively. We further extracted the pulsed X-ray emission from PSR J0058–7218 in order to constrain the pulsar’s spectral shape and luminosity which is otherwise contaminated by the underlying PWN and SNR emission in the phase averaged spectrum. A photon-index of 1.4 is consistent with that measured typically in other young rotation-powered pulsars where the non-thermal radiation is generated by the particles accelerated in the pulsar magnetosphere (see Becker & Truemper 1997; Wang & Zhao 2004).

The X-ray pulse profile of PSR J0058–7218 is single peaked with a duty-cycle of \(\approx 0.4\), and shows no apparent evolution with energy in the range of 0.4–10 keV. The measured spin-period and the spin period derivative can be used to derive the spin down luminosity (\(\dot{E}\), characteristic age (\(\tau_\text{c}\)) and the equatorial surface magnetic field (\(B_{\text{surf}}\)) of the pulsar, assuming spin-down by magnetic dipole radiation. The derived parameters of PSR J0058–7218 are given in Table 1. A spin down luminosity of \(\dot{E} \geq 10^{38} \text{erg s}^{-1}\) indicates a Crab-like pulsar making it the first such discovery in the SMC and the third in the Magellanic Clouds, the two others being PSR J0537–6910 and PSR J0540–6919 located in the 30 Doradus region of the LMC. A characteristic age of 12 kyr makes it the oldest known Crab-like pulsar. The estimated age is however in line with the Sedov age of 14.7 kyr, derived from the X-ray emission of the SNR (Owen et al. 2011).

Figure 4 shows the location of PSR J0058–7218 on the \(P–P\) diagram of pulsars, making it a close analogue of PSR J0537–6910 (the fastest rotating non-recycled pulsar in the LMC SNR N157B; Marshall et al. 1998) in terms of their spin-down properties. The radiation efficiency \(\eta_\gamma\), which is defined as the ratio of the pulsar’s non-thermal X-ray radiation luminosity to the spin-down luminosity (see e.g. Shibata et al. 2016), is also comparable for the two systems and is of the order of \(\approx 10^{-3}\). However, this is about two orders of magnitude smaller than that of the Crab pulsar and PSR J0540–6919. The observed differences (and similarities) in radiation efficiencies can be accounted for by a geometric effect mainly due to differences in the observer’s viewing angle (Takata & Cheng 2017).

---

\(^2\) https://www.cv.nrao.edu/~ransom/presto/
\(^3\) https://github.com/gajjarv/PulsarSearch
PSR J0537–6910 is also a radio-quiet pulsar, emitting non-thermal X-ray pulsed emission and without detected γ-ray pulsations. This makes it similar to our system at the current detection limits of the radio and γ-ray observations. The above observed properties could also indicate a geometric effect as the non-detection of radio emission and the thermal X-ray component imply that the polar cap region is hidden from our view. In this case, as the beaming directions of the γ-rays and the non-thermal X-rays may not be the same, our line of sight might also miss the γ-ray beam (Cheng et al. 1998; Hui et al. 2017).

The discovery of a young, energetic and ultra-fast pulsar like PSR J0058–7218 provides a unique opportunity to probe the braking mechanisms and birth-spin models of rotation-powered pulsars. Future monitoring of PSR J0058–7218 is crucial to constrain the second derivative of the period in order to measure the braking-index of the pulsar and allow deeper searches in the radio and γ-rays, and look for putative glitches that are fairly common in young rotation powered pulsars on timescales of a few years. A continuous monitoring of the spin evolution will also be very important because of its potential as a source of detectable gravitational waves (Abbott et al. 2019).
