Mechanical forces are critical to modulate cell spreading, contractility, gene expression, and even stem cell differentiation. Yet, existing tools that can apply controllable subcellular forces to a large number of single cells simultaneously are still limited. Here we report a novel ultrasound tweezing cytometry utilizing ultrasound pulses to actuate functionalized lipid microbubbles covalently attached to single live cells to exert mechanical forces in the pN - nN range. Ultrasonic excitation of microbubbles could elicit a rapid and sustained reactive intracellular cytoskeleton contractile force increase in different adherent mechanosensitive cells. Further, ultrasound-mediated intracellular cytoskeleton contractility enhancement was dose-dependent and required an intact actin cytoskeleton as well as RhoA/ROCK signaling. Our results demonstrated the great potential of ultrasound tweezing cytometry technique using functionalized microbubbles as an actutable, biocompatible, and multifunctional agent for biomechanical stimulations of cells.

Mechano-sensitivity or -responsiveness to extracellular biomechanical signals is a fundamental characteristic that controls the function of many types of mammalian cells. However, the molecular mechanism of such mechanotransduction processes is still elusive1,2. Although shear stresses and stretch forces applied to adherent mammalian cells can induce cellular responses such as reorganization of actin cytoskeleton and changes of intracellular contractile forces, it is difficult to identify cell membrane receptors responsible for force transmission and converting external mechanical signals into intracellular biochemical events at a subcellular resolution1-4. Optical1 and magnetic tweezers5,6 have been commonly employed to apply local subcellular forces using functionalized microbeads attached to cell membrane via ligand-receptor binding. Optical tweezer can apply forces typically in the piconewton (pN) range, which is suitable for manipulation of single molecules but not large enough to induce cellular functional responses5-9. Further, optical tweezer can only apply stimuli to one single cell at a time and thus is prohibitive for large-scale, high-throughput cellular functional assays involving many single cells simultaneously. Magnetic tweezer can apply local subcellular pulling force as well as twisting stress in the range of pN to nanonewton (nN) by actuating magnetic beads functionalized with specific membrane receptor ligands10. Magnetic tweezer has been successfully applied to mammalian cells to regulate gene expression and even stem cell differentiation11,12.

Given the importance of mechanical forces to modulate mechanoresponsive behaviors of cells, as well as the need of new cellular bioengineering tools for high-throughput multiparametric screening and translational applications, it is highly desirable to develop new tools with expanded capabilities that can apply controllable mechanical forces with a subcellular precision on a large number of live single cells simultaneously.

Here we report a novel acoustic tweezing cytometry technique that utilizes ultrasound excitation of membrane-bound gaseous microbubbles to generate controllable subcellular mechanical stimulations to live single cells. Microbubbles are highly responsive to ultrasound excitation owing to a large difference in acoustic impedance between gas inside bubble and surrounding liquid media. Oscillatory positive and negative pressure of an ultrasound field readily induces microbubble expansion and contraction (stable cavitation, resulting in fluid microstreaming), and/or violent collapse (inertial cavitation, which can generate high-speed fluid micro-jet that can penetrate cell membrane) if the pressure amplitude is high enough13-15. In addition to rapid volumetric expansion/contraction and collapse of microbubbles, an ultrasound field can also generate a directional force on the bubble16-18, recognized as the acoustic radiation force, which can compress the bubble against cell membrane...
to exert a mechanical force on the cell. The acoustic radiation force resulted from ultrasound stimulated microbubbles can lead to rupture of cell membrane19.

Stabilized microbubbles encapsulated by lipids or a thin protein layer have been recently developed successfully as contrast agents for ultrasound imaging in clinical diagnostic radiological applications20,21. Recently, lipid-stabilized microbubbles coated with streptavidin have been developed to enable functionalization of bubbles with specific ligands on the bubble shell encapsulating the gas core. Functionalized bubbles allow selective or targeted attachments of bubbles to mammalian cells via specific ligand–receptor binding21,22, enabling in vivo ultrasound molecular imaging by recognizing molecular markers associated with specific diseases including inflammation and angiogenesis24,25. In addition, ultrasound excitation of functionalized lipid microbubbles have been exploited for delivering cell-membrane impermeable DNAs, drugs, and other therapeutic compounds from extracellular space into cells26,27 by transiently disrupting cell membrane via stable28,29 or inertial cavitation (sonoporation)30,31. Ultrasound-induced microbubble activities can generate localized yet significant mechanical impact on cells32,33.

In this study, we developed a novel ultrasound tweezing cytometry utilizing ultrasound-exciteable microbubbles targeted to cell membrane to apply spatiotemporally controlled subcellular mechanical forces to live single cells. By applying ultrasound pulses with appropriate amplitude and duration, functionalized lipid microbubbles attached to individual cells were actuated to exert subcellular mechanical forces in the pN - nN range to live single cells. Specifically, using NIH/3T3 fibroblasts and human mesenchymal stem cells (hMSCs) as mechanosensitive cell models, we showed that ultrasonic excitation of lipid microbubbles attached on cell membrane through integrin-mediated adhesions could elicit a rapid and sustained reactive intracellular cytoskeleton contractile force increase. Such ultrasound-mediated intracellular cytoskeleton contractility enhancement was dose-dependent and required an intact actin cytoskeleton structure as well as RhoA/ROCK signaling for intracellular transmission and conversion of mechanical signals. Our results demonstrated for the first time the potential of ultrasound tweezing cytometry technique using targeted microbubbles as an actuatable, biocompatible, and multifunctional agent for biomechanical stimulation of mechano-sensitive and -responsive cells.

Results

Ultrasound tweezing cytometry to control subcellular contractile response. To study ultrasound-mediated changes in intracellular cytoskeleton contractility, we utilized an elastomeric micropost array we have recently developed as subcellular live-cell force sensors to quantify intracellular contractile forces34. The micropost array consists of an array of uniformly spaced, vertical, elastomeric posts fabricated using photolithography and replica molding with silicone elastomer polydimethylsiloxane (PDMS) (Fig. 1A). After adhesive proteins are coated using microcontact printing on the post tips, cells are able to adhere, spread out, and exert contractile forces that deflect underlying posts. Each post, therefore, functions as a cantilever, capable of measuring local cellular traction force exerted at the post tip. For tip deflections δ that are small compared to the post height L, the PDMS post can be modeled as a linearly elastic beam subjected to pure bending. Thus, intracellular contractile force F applied at the tip of the PDMS post can be calculated as $F = 3\pi Ed^3/64L^4$, where E is the elastic modulus of PDMS and d is the post diameter. In this study, NIH/3T3 fibroblasts and hMSCs were first seeded as single cells on fibronectin-coated PDMS microposts. Individual lipid microbubbles with a mean diameter of 2.3 μm and functionalized with Arg-Gly-Asp (RGD) peptides using avidin-biotin conjugation chemistry were then attached to the cells through specific binding to integrins on cell membrane (Supplementary Fig. S1). To investigate how cytoskeleton contractile force would respond to ultrasound excitation of microbubbles with membrane disruption, we applied ultrasound pulses with a greater acoustic pressure (0.13 MPa) and shorter pulse duration (8 μs) to excite microbubbles attached to cell membrane. (These parameters have been shown previously to be capable of generating sonoporation of cells with localized membrane disruption35.) Under such ultrasound stimulations, cytoskeleton...
contractile force of NIH/3T3 fibroblasts immediately decreased before slowly recovering to the contractile level prior to ultrasound treatments (top panel in Fig. 2A&B). Transcellular contractile force distributions (top panels) and pseudocolor ratio images of intracellular free calcium concentration ([Ca^{2+}]) (bottom panels) before (t < 0 min) and after US application were shown. Scale bars, 10 μm. (D) Temporal evolution of total cytoskeleton contractile force (normalized to contractility before US excitation). (E) Fluorescence ratio representing [Ca^{2+}] as a function of time. Data in D and E are shown as mean ± s.e.m. n = 31 for 10 sec US exposure, and n = 10 for 20 sec US stimulation. Control groups without MBs attached and treated with (n = 8) or without (n = 10) US were included for comparison. (F) No intracellular propidium iodide (PI) was detected in NIH/3T3 fibroblasts with MBs attached after US stimulation. Calcein AM essay showed the same cell could convert calcein AM into green fluorescent calcein and confine it within cell cytoplasm. US parameters used in Fig. 1: US frequency of 1.25 MHz, acoustic pressure of 0.05 MPa, PRF of 1 Hz, and duty cycle of 5%.

Figure 1 | Modulation of subcellular cytoskeleton contractility by ultrasound (US) excitation of microbubbles attached to cell membrane (“acoustic tweezing cytometry”). (A) A schematic showing US excitation of microbubbles (MB) attached via RGD-integrin binding to the membrane of a cell seeded on the PDMS micropost array. (B&C) Single NIH/3T3 fibroblasts with one MB (arrow head) attached to cell membrane and subjected to 10 sec (B) or 20 sec (C) US stimulations. Subcellular contractile force distributions (top panels) and pseudocolor ratio images of intracellular free calcium concentration ([Ca^{2+}]) (bottom panels) before (t < 0 min) and after US application were shown. Scale bars, 10 μm. (D) Temporal evolution of total cytoskeleton contractile force (normalized to contractility before US excitation). Subcellular distribution of cytoskeleton contractile force response. We next examined the effect of the attachment location of microbubble on subcellular distribution of reactive cytoskeleton contractile force increase. We divided NIH/3T3 fibroblasts examined in Fig. 1 into two groups based on the location of microbubble on cell membrane. In the first group (n = 15), each cell had a microbubble attached to the cell periphery region (i.e. outer 1/3 region from cell centroid) (see Methods), while in the other group (n = 16), each cell had a bubble attached to the cell central area.
Contractile force maps obtained by summation of the contractile force change for each cell with the bubble location aligned (Supplementary Fig. S4) showed that when the microbubble was attached to cell periphery, cytoskeleton contractile force enhancement was concentrated in the local subcellular area surrounding the bubble (Supplementary Fig. S4A). In contrast, when the bubble was located near cell centroid, contractile force increase was distributed evenly across entire cell area (Supplementary Fig. S4B). It should be noted that the total contractile force increase for the two cell groups was of a similar magnitude (Supplementary Fig. S4C). The dependence of subcellular distribution of reactive cytoskeleton contractile force increase on bubble attachment location was likely due to subcellular non-uniform distribution of actin cortex, known to concentrate on cell periphery to transmit and distribute reactive intracellular contractile force.

Actin, myosin II and RhoA/ROCK signaling required for cytoskeleton contractile response to ultrasound tweezing. The actin cytoskeleton consists of multiple molecular structures and components, with actin microfilaments and myosin II molecules as primary determinants for intracellular force transmission properties. RhoA/ROCK signaling is also critically involved in mechanotransduction and regulation of intracellular cytoskeleton contractility. To investigate functional roles of actin polymerization, myosin II activity and RhoA/ROCK signaling in regulating ultrasound-mediated contractile force enhancement, we treated NIH/3T3 fibroblasts with small molecule inhibitors to target specifically actin polymerization (cytochalasin D, an inhibitor of actin polymerization), myosin II activity (blebbistatin, a myosin II ATPase inhibitor), and RhoA/ROCK signaling (Y27632, a ROCK inhibitor) (Supplementary Fig. S5). NIH/3T3 fibroblasts attached with microbubbles were first treated with individual drugs for 30 min before stimulated by ultrasound. Cytoskeleton contractile forces of drug-treated NIH/3T3 fibroblasts decreased rapidly within the first 10 min after the onset of drug treatments before reaching an equilibrium contractile state at the end of the 30-min period (data not shown). More specifically, after...
Shear stress and microbubble displacement induced by ultrasound tweezing. To investigate the biomechanical mechanisms underlying ultrasonic bubble excitation-mediated cytoskeleton contractile force enhancement, we employed high-speed imaging to examine in situ bubble activities driven by ultrasound exposures. We observed that microbubbles exhibited translational movements or displacements relative to their original location on cell membrane when stimulated using ultrasound. As shown in Fig. 3A and Supplementary Video 1, using the same ultrasound condition as in Fig. 1 (acoustic pressure 0.05 MPa, center frequency 1.25 MHz, PRF 1 Hz, and duty cycle 5%), a microbubble initially bound to cell membrane was pushed away from and then pulled back to its original position repeatedly during ultrasound stimulation, and such periodic bubble displacement corresponded temporarily with pulsed ultrasound exposures. During ultrasound “pulse-on” periods, the microbubble was pushed away in the ultrasound propagation direction by the primary acoustic radiation force acting on the bubble (Fig. 3A&B). Assuming a plane ultrasound field, the maximum acoustic radiation force on a bubble with a radius of 2.3 μm was estimated to be 17.0 nN (see Methods), comparable in magnitude to mechanical forces generated by magnetic tweezers. During ultrasound “pulse-off” periods, the microbubble was pulled back partially or fully sometimes to its original position, indicating a biomechanical recovery process dictated by elastic properties of the bubble-focal adhesion-cytoskeleton mechanical linkage after release of external acoustic force.

Besides bubble displacement, the rapid volumetric expansion and contraction of microbubbles driven by ultrasound excitation can generate fluid flow (microstreaming) and thus shear stress on cells. Shear stress exerted on cells were estimated from the peak fluid flow velocity near the bubble measured using the Micron-resolution Particle Image Velocimetry (micro-PIV) (see Methods; the peak velocity was 20.15 ± 3.92 mm/s (n = 28) corresponding to a maximum shear stress exerted on cell membrane of 7.05 ± 1.41 Pa). Note that our calculation was based on the peak value of a pulsatile shear stress field surrounding a microbubble during the 10-sec pulsed ultrasound application. Thus, the time-averaged shear stress during the whole ultrasound stimulation was much less. It has been reported that sustained shear stress above a value of 1–2.5 Pa can affect behaviors of NIH/3T3 fibroblasts; however, cells examined in such studies have been exposed to a sustained shear stress for >8 hr.

A time-resolved measurement of actual bubble expansion and contraction at the ultrasound frequency of 1.25 MHz and with the ultrasound pulse of 50 ms is technically challenging and requires a frame rate above several Mframes per sec. Nonetheless, we recorded high-resolution images of microbubbles during the entire ultrasound application duration (10 sec) at a frame rate of 20 kframes per sec to assess changes of bubble size. We observed that microbubbles gradually reduced their size during ultrasound application (Fig. 3C), likely owing to disruption of bubble lipid shell during repeated bubble expansion and contraction, causing gas diffusion out of bubble. A reduction of microbubble size resulted in a decrease of acoustic radiation force acting on the bubble, leading to a shortened bubble displacement driven by later pulses as shown in Fig. 3B. The total or accumulative forward displacement of a microbubble during the entire 10-sec ultrasound application period appeared to be positively correlated with the overall cytoskeleton contractile force increase during the 30-min observation period (Fig. 3D) (R^2 = 0.72 and n = 13), suggesting the important role of the physical displacement of integrin-mediated cell adhesion in regulating cytoskeleton contractile force response. The broad distribution of accumulative displacement of microbubbles was attributable to the bubble initial size distribution (and thus different acoustic radiation forces acting on bubbles) as well as inevitable variations in RGD-integrin binding and their intracellular connection to actin cytoskeleton.

Both shear stress (due to ultrasound-driven microbubble expansion and contraction) and microbubble displacement (due to acoustic radiation force) might have contributed to reactive cytoskeleton contractile force change. The relative dominance of microbubble displacement over their expansion and contraction can be adjusted by tuning ultrasound parameters such as ultrasound frequency,
acoustic pressure, and pulse duration. Additional future work is needed to determine precisely the relative role of these two biophysical factors in ultrasonic bubble excitation-mediated cytoskeleton contractile force enhancement.

**Discussion**

Our study demonstrates that ultrasound excitation of targeted microbubbles provides a robust strategy for biomechanical stimulation of mechano-sensitive and -responsive mammalian cells. The strong contractile response of NIH/3T3 fibroblasts as well as hMSCs to ultrasound excited microbubbles suggests that our ultrasound tweezing cytometry technique may have a great utility in regulating cellular behaviors.

Cells can sense mechanical stimuli and convert them into downstream intracellular biochemical signals, and such mechanotransduction process has profound impact in many physiological and pathological contexts. For example, endothelial cells respond to blood flow shear stress by regulating actin cytoskeleton structure. Cytoskeleton contractility has also been implicated as a non-destructive live-cell predictor for hMSC differentiation. Thus, the ultrasound tweezing cytometry methodology reported here can be effectively applied, in principle, to regulate biomechanical and cellular responses of different cell types.

Like magnetic and optical tweezers, our acoustic tweezing cytometry can generate controllable localized mechanical forces to single live mammalian cells. However, acoustic tweezing cytometry has several unique advantages. Unlike microbeads used in magnetic or optical tweezers, microbubbles provide a versatile multifunctional platform that can enable multifaceted applications. Microbubbles have been established as an effective imaging contrast agent for ultrasound imaging, and they are also routinely used as drug carriers. Thus, the acoustic tweezing cytometry reported here has the potential for in vivo imaging guided manipulation of cellular contractility and thus downstream cellular effects. In addition, ultrasound excitation of targeted microbubbles is capable of intracellular delivery of drugs in a spatiotemporally controlled fashion, as we have previously demonstrated. Thus, besides direct mechanical perturbation of cells, sonoporation can be seamlessly implemented and integrated in the same platform with acoustic tweezing cytometry to deliver membrane-impermeable drugs into cells for additional biochemical modulations of intracellular signaling. Many types of mammalian cells, either adherent in a monolayer or embedded in a three-dimensional matrix, can be treated simultaneously by ultrasound stimulation that can readily excite all microbubbles within the ultrasound field, providing a high-throughput cytometric assay on a large number of single cells with a subcellular precision. Further, by focusing ultrasound field to a local region or spatially patterning microbubbles, a selected group of cells within a monolayer or other multicellular configurations can be targeted for biomechanical manipulations, thus enabling investigation of intercellular biomechanical interactions.

In summary, we demonstrated here for the first time that ultrasound excitation of targeted microbubbles could enable controlled application of subcellular biomechanical stimuli to live single cells. Drug inhibition experiments demonstrated that intact actin cytoskeleton, myosin activity, and RhoA/ROCK signaling were all required for force sensing and transmission in the acoustic tweezing cytometry system. We envision that the acoustic tweezing cytometry employing targeted microbubbles as a biocompatible and multifunctional agent can be further developed in the future as a powerful cell mechanics and mechanobiology tool to regulate cell function, gene expression, and stem cell differentiations both in vitro and in vivo.

**Methods**

**Fabrication and surface functionalization of PDMS microposts.** The PDMS micropost array was fabricated using a protocol described previously. Briefly, a silicon micropost array master was fabricated by standard photolithography and deep reactive ion etching (DRIE). The height of silicon micropost was modulated by controlling DRIE etch time. The silicon master was silanized with (tridecafluoro-1, 1, 2, 2-tetraydrooctyl)-1-trichlorosilane (United Chemical Technologies, Bristol, PA) for 4 hrs under vacuum before 1: 10 (w/w, curing agent/base monomer) ratio PDMS prepolymer (Sylgard 184, Dow-Corning, Midland, MI) was poured over the silicon master and cured at 110 C for 20 min. Negative PDMS molds were peeled off the silicon master, oxidized with oxygen plasma for 1 min (200 mTorr; Plasma Prep II, West Chester, PA), and silanized with (tridecafluoro-1, 1, 2, 2-tetraydrooctyl)-1-trichlorosilane for 24 hrs. To generate final PDMS micropost arrays, 1: 10 (w/w, curing agent/base monomer) ratio PDMS prepolymer was poured over the negative PDMS mold and degassed under vacuum for 10 min. A clean 25 mm 25 mm cover glass was then placed on top of the negative mold, and the whole assembly was cured at 110 C for 40 hrs. The final PDMS micropost array was then peeled off the negative PDMS mold. When peeling induced collapse of PDMS microposts, we regenerated the array by sonication in 100% ethanol for 30 sec followed by dry-release with liquid CO2 using a critical point dryer (Sarder-PVT-3D, Tousimis, Rockville, MD). The cover glass holding the PDMS micropost array was finally attached to a 35 mm dish with a 20 mm hole at the dish center (MatTek dish; Glass Bottom Dishes, MatTek, Ashland, MA).

To promote cell adhesion, top surface of the PDMS micropost array was functionalized with fibronectin (Sigma, St. Louis, MO) using microcontact printing. Briefly, a flat PDMS stamp made from 1: 30 (w/w, curing agent/base monomer) ratio PDMS prepolymer was soaked in a fibronectin solution (50 μg mL−1) in distilled water for 1 hr at room temperature. The PDMS stamp was then thoroughly rinsed with distilled water and blown dry with a stream of nitrogen. In parallel, the PDMS micropost arrays were treated with a UV-ozone cleaner (height, Irvine, CA). The PDMS micropost array was UV-ozone treated for 10 minutes, followed by UV-ozone surface activation. The PDMS stamp was placed in conformal contact with the PDMS micropost array for 10 sec to transfer fibronectin from the stamp to the top surface of the PDMS micropost array. The PDMS micropost array was then labeled with 5 μg mL−1 α-DiI (Invitrogen, Grand Island, NY) in distilled water for 1 hr. To prevent PDMS micropost array adhesion to fibronectin-functionalized micropost array, the PDMS micropost array was incubated in 0.1%–1% (w/v) Pluronics F127 NF (BASF, Sigma, St. Louis, MO) in distilled water for 30 min at room temperature.

**Cell culture.** NIH/3T3 mouse fibroblasts (ATCC, Manassas, VA) were maintained at 37 C and 5% CO2 in a growth medium consisting of low-glucose Dulbecco’s modified Eagle’s medium (DMEM; Invitrogen) supplemented with 10% bovine serum (Invitrogen), 1% L-glutamine and 1% penicillin/streptomycin. Human mesenchymal stem cells (Lonza, Walkersville, MD) were maintained at 37 C and 5% CO2 in the MSCGM mesenchymal stem cell growth medium (Lonza). Cells were harvested 8–16 hrs before experiments and seeded as single cells on the PDMS micropost array in the MatTek dish at a density of 3,000 cells cm−2.

**Targeted lipid microbubbles and their attachment to cells.** Targestar20–SA lipid microbubbles from Targeson (San Diego, CA) were used in this study. Microbubbles (with a mean diameter of 2.3 ± 0.2 μm; n = 39) were first mixed with biotinylated Arg-Gly-Asp (RGD) peptides (Peptides International, Louisville, KY) for 20 min at room temperature, with a molar ratio of 5: 1 for microbubbles (5 × 106 mL−1) and RGD (0.01 mg mL−1). Following a recommended procedure from the manufacturer, immediately after removal of culture media in the dish where cells were seeded on the PDMS micropost arrays, 20 μL of the microbubble-RGD mixture was added into the dish (see Supplementary Fig. S1). The dish was then flipped upside down for 10 min to allow bubbles to float up towards cells to facilitate binding of microbubbles to the cells. Unbound bubbles were removed by some gentle wash with culture media. The concentration of microbubbles used in this study ensured that for most single cells, only one bubble was attached to cell membrane.

**Ultrasonic application.** An ultrasound transducer (Advanced Devices, Wakefield, MA) driven by a function generator (Agilent Technologies 33250A, Palo Alto, CA) and a 75 W power amplifier (Amplifier Research, Souderton, PA, USA) was used to generate ultrasound pulses to excite microbubbles. The ultrasound transducer was positioned at a 45° angle relative to the horizontal MatTek dish, in order to avoid formation of standing wave in the dish and to permit unobstructed microscopic imaging. The transducer activation surface was submerged in the medium 7 mm (Rayleigh distance) away from cells. To further minimize formation of standing waves in the MatTek dish, a chip technique23 for ultrasound application was applied. Each ultrasound pulse was produced by sweeping or chirping the driving frequency around the center frequency, i.e. 1.1–1.4 MHz. The acoustic pressure amplitude of the chirped pulses was further calibrated in a free field using a needle hydrophone (HMR-0500, ONDA, CA, USA).

**Videomicroscopy and ultrasonic driven bubble activities.** Images of microbubbles excited by ultrasound exposures were acquired using a high-speed camera (FASTCAM SA1, Photron, San Diego, CA; with the frame rate up to 20 Kframes s−1) and a water immersion 60X objective (1.0 NA; Nikon, Melville, NY, USA) mounted on an inverted fluorescence microscope (Eclipse Ti-U; Nikon). Ultrasonic driven bubble activities such their trajectories and change in bubble radius were quantified using commercial image processing software (FASTCAM Viewer 3, Photron). Specifically, bubble displacement was quantified by manually locating the bubble center and tracking its position in each frame. Bubble...
radius was determined by counting pixels within a manually-defined boundary for the bubble in each frame.

Acoustic radiation force acting on microbubbles. A first-order estimate of the primary acoustic radiation force \( F \) acting on microbubbles by an ultrasound field at a resonance frequency of \( f_0 \) was obtained from \( F = 2\pi CP_0R_b(\text{doppler}A_c)/c^2 \), where \( P_0 \) is the acoustic pressure, \( R_b \) is the bubble radius, \( A_c \) is the total damping constant (\( \text{doppler}A_c = 0.16 \)), \( P_0 \) is the medium density (1000 kg m\(^{-3}\)), and \( c \) is the sound speed in medium (1500 m s\(^{-1}\)). It should be noted that this estimation did not consider the effect of the lipid shell on resonant frequency.

Flow velocity and shear stress generated by ultrasound excitation of microbubbles. Ultrasound driven microbubble expansion and contraction generates microstreaming or flow field near the bubble. We applied the micromesh-resolution Particle Image Velocimetry (micro-PIV) to measure flow velocity near a bubble, by using 0.5 \( \mu \)m diameter polystyrene particles (Thermo Scientific, CA, USA) as flow tracers. Specifically, tracer particles at a stock solution (1.46 \( \times 10^{12} \) particles ml\(^{-1}\)) were diluted first in deionized water with a 1:2 (v/v) ratio. 2 \( \mu \)l of diluted tracer solution was then added to culture media right before ultrasound applications for cells seeded on the PDMS micropost array in the MatTek dish. Positions of tracer particles near a bubble during ultrasound application were continuously recorded using the high-speed camera at a frame rate of 20 Kframes s\(^{-1}\). Velocities of polystyrene particles and thus the flow field near the bubble were obtained by processing the image sequence using Image J (US National Institutes of Health, Bethesda, MD). Shear stress \( \tau \) exerted on cell membrane due to microstreaming of fluid was then calculated as \( \tau = \pi \mu \Delta v \), where \( \mu \) is the medium viscosity (7.26 \( \times 10^{-3} \) Pa s), \( \Delta v \) is the flow velocity difference between bubble equator plane and cell membrane, and \( \Delta y \) is treated equal to the bubble radius.

Fluorescence imaging. An air-cooled CCD camera (Photometrics QuantEM, Tucson, AZ, USA) was used for fluorescence imaging. Calcium imaging was performed using a method described previously\(^{11}\). Briefly, cells seeded on the PDMS micropost array were treated with 10 \( \mu \)M Fura2-AM (Invitrogen) and 0.05% (w/v) Pluronic F-127 (Invitrogen) in culture media for 60 min at 37\(^\circ\)C and 5% CO\(_2\). Fluorescence emission intensities of Fura2 at 510 nm from cells excited at wavelengths of 340 nm and 380 nm were acquired to generate ratiometric images. Fluorescence emission intensities of Fura2 at 510 nm from cells excited at 320 nm, 340 nm, 380 nm, and 400 nm were acquired to generate fluorescence ratiometric images. A first-order estimate of the primary acoustic radiation force acting on microbubbles was obtained from the following equations:

\[
\text{Acoustic radiation force, } F = 2\pi CP_0R_b(\text{doppler}A_c)/c^2 \\
\text{where, } P_0 \text{ is the acoustic pressure, } R_b \text{ is the bubble radius, } A_c \text{ is the total damping constant (dopplerA_c = 0.16), } P_0 \text{ is the medium density (1000 kg m}^{-3}\text{), and } c \text{ is the sound speed in medium (1500 m s}^{-1}\text{). It should be noted that this estimation did not consider the effect of the lipid shell on resonant frequency.}
\]

Flow velocity and shear stress generated by ultrasound excitation of microbubbles. Ultrasound driven microbubble expansion and contraction generates microstreaming or flow field near the bubble. We applied the micromesh-resolution Particle Image Velocimetry (micro-PIV) to measure flow velocity near a bubble, by using 0.5 \( \mu \)m diameter polystyrene particles (Thermo Scientific, CA, USA) as flow tracers. Specifically, tracer particles at a stock solution (1.46 \( \times 10^{12} \) particles ml\(^{-1}\)) were diluted first in deionized water with a 1:2 (v/v) ratio. 2 \( \mu \)l of diluted tracer solution was then added to culture media right before ultrasound applications for cells seeded on the PDMS micropost array in the MatTek dish. Fluorescence emission intensities of Fura2 at 510 nm from cells excited at wavelengths of 340 nm and 380 nm were acquired to generate ratiometric images. A first-order estimate of the primary acoustic radiation force acting on microbubbles was obtained from the following equations:

\[
\text{Acoustic radiation force, } F = 2\pi CP_0R_b(\text{doppler}A_c)/c^2 \\
\text{where, } P_0 \text{ is the acoustic pressure, } R_b \text{ is the bubble radius, } A_c \text{ is the total damping constant (dopplerA_c = 0.16), } P_0 \text{ is the medium density (1000 kg m}^{-3}\text{), and } c \text{ is the sound speed in medium (1500 m s}^{-1}\text{). It should be noted that this estimation did not consider the effect of the lipid shell on resonant frequency.}
\]

Flow velocity and shear stress generated by ultrasound excitation of microbubbles. Ultrasound driven microbubble expansion and contraction generates microstreaming or flow field near the bubble. We applied the micromesh-resolution Particle Image Velocimetry (micro-PIV) to measure flow velocity near a bubble, by using 0.5 \( \mu \)m diameter polystyrene particles (Thermo Scientific, CA, USA) as flow tracers. Specifically, tracer particles at a stock solution (1.46 \( \times 10^{12} \) particles ml\(^{-1}\)) were diluted first in deionized water with a 1:2 (v/v) ratio. 2 \( \mu \)l of diluted tracer solution was then added to culture media right before ultrasound applications for cells seeded on the PDMS micropost array in the MatTek dish. Positions of tracer particles near a bubble during ultrasound application were continuously recorded using the high-speed camera at a frame rate of 20 Kframes s\(^{-1}\). Velocities of polystyrene particles and thus the flow field near the bubble were obtained by processing the image sequence using Image J (US National Institutes of Health, Bethesda, MD). Shear stress \( \tau \) exerted on cell membrane due to microstreaming of fluid was then calculated as \( \tau = \pi \mu \Delta v \), where \( \mu \) is the medium viscosity (7.26 \( \times 10^{-3} \) Pa s), \( \Delta v \) is the flow velocity difference between bubble equator plane and cell membrane, and \( \Delta y \) is treated equal to the bubble radius.

Fluorescence imaging. An air-cooled CCD camera (Photometrics QuantEM, Tucson, AZ, USA) was used for fluorescence imaging. Calcium imaging was performed using a method described previously\(^{11}\). Briefly, cells seeded on the PDMS micropost array were treated with 10 \( \mu \)M Fura2-AM (Invitrogen) and 0.05% (w/v) Pluronic F-127 (Invitrogen) in culture media for 60 min at 37\(^\circ\)C and 5% CO\(_2\). Fluorescence emission intensities of Fura2 at 510 nm from cells excited at wavelengths of 340 nm and 380 nm were acquired to generate ratiometric images. A first-order estimate of the primary acoustic radiation force acting on microbubbles was obtained from the following equations:

\[
\text{Acoustic radiation force, } F = 2\pi CP_0R_b(\text{doppler}A_c)/c^2 \\
\text{where, } P_0 \text{ is the acoustic pressure, } R_b \text{ is the bubble radius, } A_c \text{ is the total damping constant (dopplerA_c = 0.16), } P_0 \text{ is the medium density (1000 kg m}^{-3}\text{), and } c \text{ is the sound speed in medium (1500 m s}^{-1}\text{). It should be noted that this estimation did not consider the effect of the lipid shell on resonant frequency.}

This work is supported in part by the National Science Foundation (CMMI 1129611 and CBET 1149401 to J.F.), the American Heart Association (Scientist Development Grant, 12SDG12180025 to J.F.), the National Institutes of Health (CA116592 to C. X. D.), departments of Mechanical Engineering and Biomedical Engineering of the University of Michigan, The Lurie Nanofabrication Facility at the University of Michigan, a member of the National Nanotechnology Infrastructure Network (NNIN) funded by the National Science Foundation, is acknowledged for support in microfabrication.

Author contributions
C.X.D. and J.F. developed initial concept. Z.F., Y.S., D.C. designed experiments. Z.F., Y.S., D.C. and W.C. performed experiments and analyzed data. D.T. analyzed data. Z.F., Y.S., D.C. and J.F. co-wrote the manuscript. C.X.D. and J.F. supervised the study. All authors discussed the results and commented on the manuscript.
