\textbf{ABSTRACT}

The thermal evolution of hypernuclear compact stars is studied for stellar models constructed on the basis of covariant density functional theory in Hartree and Hartree-Fock approximation. Parametrizations of both types are consistent with the astrophysical mass constraints on compact stars and available hypernuclear data. We discuss the differences of these density functionals and highlight the effects they have on the composition and on the cooling of hypernuclear stars. It is shown that hypernuclear stars computed with density functional models that have a low symmetry energy slope, $L$, are fairly consistent with the cooling data of observed compact stars. The class of stellar models based on larger $L$ values gives rise to the direct Urca process at low densities, which leads to significantly faster cooling. We conjecture high-density pairing for protons and $\Lambda$'s in the $P$-wave channel and provide simple scaling arguments to obtain these gaps. As a consequence the most massive stellar models with masses $1.8 \leq M/M_\odot \leq 2$ experience slower cooling by hyperonic dUrca processes which involve $\Lambda$'s and protons.

\textbf{Key words:} dense matter – stars: neutron – stars: thermal evolution

\section{1 INTRODUCTION}

The interest in the hyperonization of matter at high densities in compact stars was rekindled in the last decade by the observations of several white dwarf–pulsar binaries with pulsar masses close to two solar masses (Demorest et al. 2010; Antoniadis et al. 2013; Fonseca et al. 2016; Barr et al. 2017). This problem was studied mainly within the density functional theory based on the Hartree (mean-field) approximation to obtain the equation of state (EoS) of matter (Weissenborn et al. 2012a, b; Bonanno & Sedrakian 2012; Bednarek et al. 2012; Long et al. 2012; Colucci & Sedrakian 2013; Miyatsu et al. 2013; Van Dalen et al. 2014; Gusakov et al. 2014; Maskov et al. 2015; Gomes et al. 2015; Oertel et al. 2015; Fortin et al. 2016; Tolos et al. 2016; Fortin et al. 2017; Marques et al. 2017; Spinella 2017; Li et al. 2018a, b; Spinella & Weber 2018). Density functionals for hypernuclear matter and its EoS were recently constructed on the basis of Hartree-Fock theory (Li et al. 2018a, b). Including the Fock contribution in the treatment allows one to introduce the pion (and more generally tensor forces) explicitly, thus achieving a more versatile representation of the density functional. In this work we will include these EoS in our study of the cooling behavior of hypernuclear stars thus extending the pool of EoS from which our models are built (Raduta et al. 2018); hereafter Paper I. Another purpose of this work is to examine how changes in the patterns of the high-density pairing affect the cooling of hypernuclear stars. It was observed that the most massive hypernuclear stars cool very fast by the $p\Lambda$ direct Urca (hereafter dUrca) process (see Paper I). The fast cooling arises because these stars develop cores where protons and $\Lambda$’s are unpaired, as their partial densities exceed the density at which the $^1S_0$ pairing gap closes. As is well known, neutron matter supports $^3P_2$-$^3F_2$ pairing at densities beyond the density for $^1S_0$ pairing. We conjecture here that the same occurs for the protonic and $\Lambda$ components of dense matter. Below, we will use simple estimates of the gaps for protons and $\Lambda$’s, which are based on the
symmetries of nuclear and hypernuclear forces, to gauge the effect of high-density pairing on the cooling of massive hypernuclear stars.

The early studies of the cooling of hypernuclear stars did not include the high-mass astrophysical constraint on the EoS of hypernuclear matter (Haensel & Gnedin 1994; Schaab et al. 1998; Tsuruta et al. 2009). In Paper I we started a systematic study of the cooling of hypernuclear compact stars on the basis of modern density functionals mentioned above. Several works have appeared since then in this context: Grigorian et al. (2018) used the “nuclear medium cooling” scenario (Blaschke et al. 2004; Schaab et al. 1997) to account for hyperons using an EoS based on the density functional theory (Schaab et al. 1998), pion-mediated enhanced neutrino emissivities for the modified Urca and bremsstrahlung processes, vanishing P-wave neutron pairing, and phenomenological crust-core temperature relation. The pion-mediated enhanced neutrino emissivities and vanishing P-wave neutron pairing are the key factors that distinguish their models from those in Paper I. Nevertheless, the remainder of the physical input, for example, the crust-core temperature relation, is not identical to ours. Note that Paper I does not implement the minimal cooling scenario (Page et al. 2004) as it allows for the direct dUrca process among nucleons and hyperons, uses pair-breaking processes with dressed (in-medium) vertices, and covers a wide range of masses up to the maximum mass of $M_{\text{max}}/M_\odot \sim 2$, which implies a varying cooling behavior for the mass hierarchy (see, in particular, the conclusion Section of Paper I). The same problem was also addressed by Negreiros et al. (2018) using hyperonic EoS based on the FSU class of relativistic density functional models which feature massive objects and are tuned to available data on hypernuclei (Tolos et al. 2017b,a). In these models, the main cooling agents are the ($\Lambda$, $p$) and ($n$, $p$) dUrca processes which were regulated by variations of proton and neutron superfluid gaps. In particular the density range over which the proton S-wave gap is non-zero has been explored with the aim to obtain a satisfactory agreement with the data. The main difference with respect to Paper I is the absence of pairing in the hyperonic sector. Combined, the emerging new generation of cooling models of hypernuclear stars have the potential to further constrain the physics of dense nuclear matter, especially its composition.

This work is structured as follows. In Sec. 2 we review the EoS models used in our cooling simulations. We discuss the stellar parameters (mass, radius, etc.) and the range of Fermi momenta of dominant particles predicted by these models. Section 2.1 is devoted to the discussion of P-wave pairing of protons and $\Lambda$’s. Simple symmetry arguments are used to extract the values and density dependences of the corresponding gaps. The critical temperatures of various species are mapped on the internal radius of the models and the pairing patterns inside the star are discussed. The results of numerical simulations of the thermal evolution of hypernuclear compact stars are shown in Section 3. A short summary of our results along with conclusions is given in Section 4.

![Figure 1. Equation of state (top), mass vs. radius relation (middle), and mass vs. central baryonic number density (bottom) for the stellar models considered in this work. For comparison, the predictions of the purely nucleonic APR EoS (Akmal et al. 1998) are represented as well. The solid (open) dots in the $P(\epsilon)$ plot show maximum-mass ($1.4M_\odot$) neutron stars (NSs). In the $M - R$ diagram open triangles, dots and squares correspond to NS whose central densities equal $n_0$, $2n_0$, and $3n_0$, respectively. The shaded horizontal stripes in the middle and bottom panels show the observed masses of pulsars PSR J0348+0432 ($M = 2.01 \pm 0.04M_\odot$ (Antoniadis et al. 2013)) and PSR J1614-2230 ($M = 1.93 \pm 0.02M_\odot$ (Fonseca et al. 2016)).](image-url)
2 EQUATION OF STATE AND PAIRING

We consider a set of equations of state which describe hypernuclear matter within the relativistic density functional theory (DFT) of nuclear matter. In addition to the three Hartree models that were studied in Paper I, here we add to our collection four Hartree-Fock (HF) models for the EoS of hypernuclear matter (Li et al. 2018a,b). In contrast to Hartree models, the HF models account for the tensor interaction between the baryons and include π-meson exchanges in addition to the σ, ω, ρ and possibly φ meson exchanges included in the Hartree models. The key nuclear properties of these models are displayed in Table 1. With the nuclear saturation density and energy per particle well constrained, the list shows the range of values of the nuclear compressibility $K$, symmetry energy $J$, and its slope $L$. Note that all HF models are characterized by large values of $L$ with the PKA1 parametrization having the largest $J$ and $L$ values. These are at the boundaries inferred from experimental nuclear physics data (Tsang et al. 2012; Lattimer & Steiner 2014). Table 2 lists the meson content of each model. The vector meson-hyperon coupling constants were chosen in each case on the basis of either the SU(3) or SU(6) spin-flavor symmetric quark model (see column 3 of Table 2). The coupling of the scalar meson to hyperons are tuned such as to reproduce the depths of the hyperon potential in symmetric saturated nuclear matter. DDME2, GM1A and SWL use the values $U^{(N)}_\Lambda \approx -28$ MeV, $U^{(N)}_\Sigma \approx -18$ MeV and $U^{(N)}_\Xi \approx 30$ MeV (Millener et al. 1988), while the PK parametrizations use $U^{(N)}_\Lambda \approx -30$ MeV, $U^{(N)}_\Sigma \approx -14$ MeV and $U^{(N)}_\Xi \approx 30$ MeV. We note here the sensitivity of our results to the value of the hyperon potential in symmetric saturated nuclear matter. Changing it from $U^{(N)}_\Lambda \approx 30$ MeV to the less repulsive value of $U^{(N)}_\Lambda \approx 10$ MeV lowers, within DDME2, the $\Sigma$ threshold below that for the $\Lambda$ hyperon (Colucci & Sedrakian 2013; Providencia et al. 2018).

The EoS of hypernuclear matter used in the present study are displayed in the upper panel of Fig. 1. For comparison, we also show in this figure the purely nucleonic non-relativistic microscopic EoS of Akmal et al. (1998) (APR) which is frequently used in cooling simulations of nucleonic NSs. As can be seen, the APR EoS is significantly softer than the relativistic DFT based EoS for $n \lesssim 4n_0$ but becomes markedly stiffer at higher densities. This has important consequences for the theoretically established pressure and energy density values at the centers of compact stars. For instance, as shown in Fig. 1, the central energy density of a 1.4 $M_\odot$ APR star is by a factor of two larger than the energy densities obtained for our EoS.

The mass-radius and mass-central-density dependencies are shown in the middle and bottom panels of Fig. 1. As can be seen, all models considered in our study satisfy the $M \approx 2M_\odot$ NS mass constraint. The GM1A and PKO models have $P(n,N)$ dependences and $L$ values close to each other such that the neutron stars with high enough ($n_c \geq 3n_0$) central densities have similar masses and radii. The differences just above the saturation density are reflected in variations of the radii of these models. The relativistic Hartree models DDME2 and SWL predict radii of the order of 13 km, while the HF based models tend to predict larger radii, on the order of 14 km. The recent detection of gravitational waves from GW170817 places an upper limit on the NS tidal deformability, and provides evidence that the radii of the merging NSs was $R \lesssim 13.7$ km (Abbott 2017; Paschalidis et al. 2018; Fattoyev et al. 2018; Annala et al. 2018; Christian et al. 2019; Tews et al. 2019) with some uncertainty in the masses. The total mass of the binary is in the range $2.37 \lesssim M/M_\odot \lesssim 2.78$, which is split among the members of the binary in the range $1.36 \lesssim M/M_\odot \lesssim 1.6$ for one star and $1.17 \lesssim M/M_\odot \lesssim 1.36$ for the other. Note that the limit on the radius is extracted from the measured tidal deformability. The value of the radius is clearly related to the value of $L$, where smaller radii correspond to smaller $L$ values (see Table 2). The bottom panel of Fig. 1 shows that those EoS which are soft up to densities $\lesssim 4n_0$ produce intermediate mass NS with high-density cores.

A more quantitative overview of the properties of hypernuclear neutron stars is given in Table 2 for the EOS of this work. The central density of the maximum mass star (fourth column), the value of the maximum mass (fifth column) and the density at which the first hyperon species appears (columns 6 and 7) have, remarkably close to each other (exceptions are $n_{\text{max}}$ for PKA1 and $n_{\Lambda}$ for the SWL model). The differences in the models are larger for the remaining entries of the table, as these are controlled by the high-density behavior of the EoS. An important difference concerns the onset of the nucleonic dUrca process (column 15 of Table 2). DDME2 does not allow for this process in stable stars. The SWL models only allow for it at very high densities ($n \gtrsim 0.9$ fm$^{-3}$). Finally the other models predict considerably lower dUrca thresholds ($\sim 0.3$ fm$^{-3}$). We also note the (negative) correlation between the value of $L$ and the threshold density of the Urca process (column 15 of Table 2).

Furthermore, it is important to discuss the particle content of the models under consideration, as the thermal evolution significantly depends on the composition of matter. Rather than showing the abundances of particles [see, for instance, Paper I and Li et al. (2018a,b)], we show in Fig. 2 the Fermi momenta of the most abundant particle species, neutrons (top), protons (middle) and $\Lambda$ (bottom). We also show the range of momenta over which neutron $P$-wave pairing and proton and $\Lambda$ $S$-wave pairing occurs, as calculated by Ding et al. (2016) [using the Argonne v18 (Wiringa et al. 1995) interaction with both short- and long-range correlations], Chen et al. (1993) and Raduta et al. (2018), respec-

**MNRA 000, 1–77**
Chen et al. shows the Fermi momenta where proton Fermi momenta obtained for the low-mass stars feature proton Fermi momenta in the centers of NSs computed for the low-mass stars, and the latter study includes only long-range correlations. The main effect of neutron S-wave superfluidity pairing in the crusts is to regulate the thermalization of the crust. In the absence of the nucleonic dUrca process, a high crustal superfluidity enhances cooling. The opposite effect occurs if the nucleonic dUrca operates. Neutron pairing in the crust impacts the cooling mainly over a time span of $t \lesssim 10^4$ yr, during which the star is not yet isothermal and the surface temperature is controlled by the crust. Therefore, the variations in the gap value are not significant for the interpretation of the data of such stars. The proton S-wave pairing gap, which is non-zero in the star’s core, plays an important role for regulating dUrca processes involving protons. In particular, this pairing gap regulates the $\Lambda$ channel of the hyperonic dUrca process, as discussed in Paper I and by Grigorian et al. (2018) and Negreiros et al. (2018). Here we adopt the proton gap of Chen et al. (1993) which covers the largest range of momenta and has a relatively large maximum of the order of 1 MeV. Thus, the suppression ef-

Figure 2. Fermi momenta of neutrons (top), protons (middle) and Λ (bottom) in the centers of NS of different masses, for the collection of EoS of this work. The horizontal dotted lines mark the upper limits (top and middle panel) or the boundaries (bottom panel) of the momentum range for which neutron, proton and Λ pairing occurs. Neutron P-wave pairing results are from Ding et al. (2016). For proton S-wave pairing we used results from Chen et al. (1993). The Λ S-wave pairing is obtained from the BCS equation (see text for details).

We have (re)computed the Λ 1S0 pairing gaps within the standard BCS theory, as described in Paper I. The pairing interaction used is the one given by ESC00 (Rijken 2001), which is one of the most attractive Λ-Λ interactions available. The suppression of dUrca processes involving Λ’s is thus maximized. Note that the Λ S-wave superfluidity occurs for Fermi momenta 0.2 \( \leq k_{F\Lambda} \leq 1.3 \) fm\(^{-1}\), which is about the same range as for S-wave neutron and proton condensates (see Fig. 3). In computing the gaps we use the background matter composition provided by an EoS chosen from our collection. This also provides us with the single particle spectrum of Λ’s in the normal state via the Λ effective Dirac mass. It is seen that the gaps are in the range 0.5 \( \leq \Delta_{\Lambda} \leq 1.2 \) MeV, which is comparable to the proton pairing gap. We thus anticipate a competition of these two pairing channels when considering the suppression of the Λp channel of the hyperonic Urca process.

The P-wave pairing of neutrons is harder to compute as the interactions are not constrained by the phase-shift analysis in the high-energy domain needed for this chan-
To illustrate the range of theoretical possibilities we present two models of the $^3P_2$-$^3F_2$ pairing gap, which are shown in Fig. 4. The computations of Ding et al. (2016) account for short- and long-range correlations and cover the Fermi-momentum range $1.15 \leq k_F \leq 2.1$ fm$^{-1}$ with the gap maximum at $\Delta \simeq 0.074$ MeV at $k_F = 1.8$ fm$^{-1}$. The gap of Ding et al. (2016) is taken as a lower bound on the gap. As an upper limit on the $P$-wave pairing gap we adopt the result of Baldo et al. (1998), which covers a significantly broader range of momenta. The maximum of this gap ($\Delta \sim 0.3$ MeV at $k_F \sim 2.15$ fm$^{-1}$) is a factor of four larger than the gap of Ding et al. (2016). In passing we note that a number of studies of the cooling of NSs assumed a vanishing $^3P_2$-$^3F_2$ pairing gap [see Beznoy et al. (2018); Grigorian et al. (2018); Negreiros et al. (2018)]. This assumption improves the agreement of the cooling curves with the data on surface temperatures of some compact objects, but it may lack any theoretical underpinning. In one of the scenarios considered in this paper, we shall make this assumption as well.

2.1 BCS $P$-wave pairing for protons and $\Lambda$’s

We have previously addressed the Bardeen-Cooper-Schrieffer (BCS) pairing among hyperons in the low-density limit, where the most attractive partial wave is the $^1S_0$ channel. In this case hyperons are paired in spin-singlet Cooper pairs. Note that within the hypernuclear mixture of particle, pairing among the different species is strongly disfavored by the particle mass differences (except for neutrons and protons, in which case the pairing is suppressed by their large difference in number density).

The $^1S_0$ gaps for $\Lambda$ hyperons were computed using the non-relativistic BCS equation for a given hyperon-hyperon potential, whereas the single-particle and particle composition were computed for the relativistic DF method, as described in Paper I. [See also the related earlier work hyperonic pairing by Balberg & Barnea (1998), Wang & Shen (2010) and Takatsuka et al. (2001).] Computing the single-particle energies and pairing gaps for different theories is not consistent formally, but in practice such an approach has been proven to work well for finite nuclei (Vretenar et al. 2005; Kucharek & Ring 1991). It is also in line with the so-called decoupling approximation which has been applied to the many-body treatment of nuclear pairing [for a review, see (Sedrakian & Clark 2018)]. We recall that for the $\Lambda\Lambda$ pairing interaction we used the configuration-space parameterization of the ESC00 potentials (Rijken 2001) given by Filikhin & Gal (2002). The potential was chosen in such a manner as to maximize the pairing gap, i.e., to provide an upper limit on the values of the gap function. Note also that the $\Sigma\Sigma$ pairing was disregarded, though this possibility has been previously considered (Vlaňa & Tokí 2004; Nishizaki et al. 2002) and gaps as large as several MeV have been obtained.

On the basis of the (approximate) isospin invariance of nuclear forces, it is natural to anticipate that $^3P_2$-$^3F_2$ pairing should also occur in the proton component, for the range of densities where this channel dominates the attraction among protons. To get an estimate of pairing gap of this channel, we account for the difference between the density of states of neutrons and protons, which amounts to replacing the neutron Landau mass $m_n^*$ by the proton Landau mass $m_p^*$. This implies a rescaling of the dimensionless pairing interaction by the factor $\alpha_{P}^{-1} = m_n^*/m_p^*$. The result is the weak-coupling estimate for the $P$-wave pairing gap for protons as

$$\Delta_p = \epsilon_{F_p} \left( \frac{\Delta_n}{\epsilon_{F_n}} \right)^{\alpha_{P}},$$  \hspace{1cm} (1)$$

where $\epsilon_{Fi}$ is the Fermi energy of baryon $i$. Thus, from the $P$-wave pairing gap for neutrons and the Fermi energies of particles, we obtain an estimate of the $P$-wave pairing gap for protons. Equation (1) follows directly from the BCS formula $\Delta_i = \epsilon_{Fi} \exp[-1/(\nu_i V_i)]$, where $\nu_i$ and $V_i$ are the density of states and the pairing matrix element for a baryon of type $i$.

We further speculate about $P$-wave pairing among $\Lambda$’s. An estimate of this pairing gap follows from the strategy adopted for protons, except that now we additionally rescale the pairing interaction among neutrons by a factor of 2/3 according to the SU(6) flavor quark model. This means that the dimensionless pairing interaction is rescaled by the factor $\alpha_{\Lambda}^{-1} = 2m_n^*/3m_\Lambda^*$ and, therefore,

$$\Delta_\Lambda = \epsilon_{F_\Lambda} \left( \frac{\Delta_n}{\epsilon_{F_n}} \right)^{\alpha_{\Lambda}}.$$  \hspace{1cm} (2)$$

Figures 5 and 6 show the critical temperature profiles for protons and $\Lambda$’s inside of NSs with masses of $1.8 M_\odot$ (top) and $2 M_\odot$ (bottom). The proton $^3S_0$-pairing has been determined according to Chen et al. (1993). The $^3P_2$-$^3F_2$-pairing gap of protons is obtained by the re-scaling procedure described just above, using Eqs. (1) and (2). For the neutron $^3P_2$-$^3F_2$-pairing the results of Baldo et al. (1998) have been used. The double-bell shaped structures in the lower panel of Fig. 5 arises because of the two ($S$- and $P$-wave) pairing channels, each channel giving rise to a maximum. Because of their low density, one would expect that the protons would be superfluid in the entire stellar core, but we note that in certain regions the critical temperature may be so low that it falls below the stellar temperature. In this event proton superfluidity will disappear and therefore will be unimportant for the suppression of neutrino radiation from the stellar core. Thus, while $P$-wave pairing of protons provides an efficient mechanism for the suppression of neutrino radiation, its actual occurrence depends on the adopted EoS and on
the density range covered by the mass model. Note that the critical temperature for the S-wave pairing has a maximum value of \( T_{c,p} \approx 7 \times 10^9 \) K, whereas for P-wave pairing this is of the order of \( 10^8 \) K or less. We conclude that for most of the EoS of this study there exist domains, either in the inner core or at the boundary between inner and outer core, where \( T_{c,p} \) is too low to efficiently suppress cooling via dUrca process involving protons.

For both masses shown in Fig. 6 \( \Lambda \) hyperons are in the S-wave superfluid state in the outer core (with \( T_{c,\Lambda} \) in the range of \( 3 - 7 \times 10^9 \) K, depending on the EoS and the star’s mass). The effect of P-wave pairing is seen whenever a double bell structure appears. The maximum appearing for large internal radius corresponds to the S-wave pairing, whereas the one appearing for small internal radius - to the P-wave pairing. The radial changes of \( T_{c,\Lambda} \) as seen in Fig. 6, can be attributed to the different fractions and effective masses of the \( \Lambda \) particle, as predicted by different EoS. For a large enough \( \Lambda \) population we find a P-wave \( \Lambda \) superfluid in the inner core for a number of models. The values of \( T_{c,\Lambda} \) are typically between \( 2 \times 10^8 \) and \( 1.5 \times 10^9 \) K. As in the case of protons, in most cases, there exists a shell between the S- and P-wave condensate where pairing almost vanishes.

In conclusion, it is clearly seen that in the absence of proton and \( \Lambda \) P-wave pairing, NSs cool rapidly (as already demonstrated in Paper I) via the dUrca process \( \Lambda \rightarrow p + l + \bar{\nu}_l \), where \( l \) stands for a lepton. This will be different if high-density P-wave pairing of protons and \( \Lambda \)'s occurs, which suppresses the dUrca process (see Sec. 3 below for explicit examples).

### 3 THERMAL EVOLUTION OF HYPERNUCLEAR STARS

We have performed a large number of cooling simulations of stellar models based on our EoS collection of hypernuclear stars described above. We assume spherically symmetric configurations of isolated self-gravitating NSs which are non-rotating and non-magnetized. Heating sources were not considered. Our collection of EoS was supplemented with the crust EoS of Negele & Vautherin (1973) and Haensel et al. (1989), which is smoothly joined together with the core EoS. The outer envelope of the star is assumed to consist of Fe. Note that young stars are believed to have He or C atmospheres. Light-element envelopes lead to surface temperatures which are higher than those produced by heavy-element envelopes. This means that the use of a Fe envelope throughout the entire evolution artificially diminishes the effective temperature of young stars and partially compromises the agreement with the X-ray data on their thermal emission.
Our models were evolved in time from some initial temperature distribution at an initial time assuming that the structure of the models does not change in time. As in Paper I, we employ an extension of the public domain NSCool code\(^1\) to include the hyperonic component with its radiation processes. These include the hyperonic d\'Urca processes (Prakash et al. 1992)

\[
\Lambda \rightarrow p + l + \bar{\nu}_l, \quad (3)
\]

\[
\Sigma^- \rightarrow \left( \frac{n}{\Sigma^0} \right) + l + \bar{\nu}_l, \quad (4)
\]

\[
\Xi^- \rightarrow \left( \frac{\Lambda}{\Xi^0} \right) + l + \bar{\nu}_l, \quad (5)
\]

\[
\Xi^0 \rightarrow \Sigma^+ + l + \bar{\nu}_l, \quad (6)
\]

where \(l\) stands for a lepton, either electron or muon, and \(\bar{\nu}_l\) is the associated antineutrino. In addition, we include the neutrino emission via the Cooper pair-breaking and formation (PBF) mechanism:

\[
\{YY\} \rightarrow Y + Y + \nu + \bar{\nu}, \quad Y + Y \rightarrow \{YY\} + \nu + \bar{\nu}, \quad (7)
\]

where \(\{YY\}\) stand for a hyperonic Cooper pair. The PBF processes were included also for nucleonic \(S\) - and \(P\)-wave superfluids. For the \(S\)-wave \(A\) condensate, we use the rate derived in Paper I. For the \(P\)-wave hyperonic condensate we adopt the emission rate derived for neutrons (Leinson 2018) with appropriate changes in the condensate parameter and weak charges.

Our strategy in studying the cooling of hypernuclear compact stars is to vary the masses of the stars in the range between 1 to 2\(M_\odot\). As pointed out in Paper I, there is a mass hierarchy in the cooling behavior, with higher mass stars cooling faster than lower mass stars. Another aspect of our study is to vary the input pairing gaps in order to quantify their effect on cooling behavior. We input three nucleonic gaps: the neutron \(1S_0\), proton \(3P_2\), and proton \(1S_0\) gap. These form a \textit{triplet} of \textit{pairing gaps}. Our strategy will be to use alternate gap inputs in such a triplet. The first triplet is defined as SFB-0-CCDK, where the acronyms SFB and CCDK refer to gaps of Schwenk et al. (2003) and Chen et al. (1993), and the number 0 stands for zero pairing gap. The second triplet of pairing gaps is DingS-DingP-CCDK, where DingS and DingP refer to the \(1S_0\) and \(3P_2\) gaps obtained by Ding et al. (2016). The hyperonic \(\Lambda \, 1S_0\) pairing is based on our CCSB computation with background matter properties specified by the corresponding EOS. It is added to each triplet of nucleonic gaps. Contrary to what we have done in Paper I, here we disregard pairing of \(\Xi\) hyperons. The rationale is to not mask the effect of the high-density pairing of protons and \(\Lambda\)’s. \(\Sigma\)'-pairing is also disregarded. Simulations were conducted with and without \(P\)-wave pairing for \(\Lambda\)’s and protons in the high-density regime to quantify their effect; their values were obtained via the scaling procedure described above. In the case of SFB-0-CCDK/DingS-DingP-CCDK, \(P\)-wave pairing for \(\Lambda\)’s and protons is calculated based on neutron \(P\)-wave pairing of Baldo et al. (1998)/Ding et al. (2016).

\(1\) www.astroscu.unam.mx/neutrones/NSCool

Our survey of cooling models shows that they can be separated, broadly speaking, into two groups. The first group which is characterized by low-\(L\) values are the Hartree models DDME2 and SWL. The second group associated with large-\(L\) values comprises the GM1A model and all the HF models. As shown above, these two groups are characterized by high and low nucleonic d\'Urca thresholds, respectively. Below we discuss them separately and display for the second group only the results obtained for the PKA1 and PKO3 EOSs. Figures 7 and 8 show the cooling tracks for different mass models for these two groups of EOS. For each group, the various panels include or exclude the high-density \(P\)-wave pairing.

Before turning to the discussion of the features specific to different EOS it is useful to point out the common features seen in the cooling simulations. (a) There is a mass hierarchy with respect to the speed of cooling - the heavier stars cool faster than the light ones. (b) Neutrino emission due to the PBF processes in a neutron \(P\)-wave superfluid in the core leads to accelerated cooling after \(t \geq 10^3\) yr. This acceleration is substantial even for the smallest gaps adopted here (DingP). As a consequence, the cooling tracks undershoot the observational value of the temperature of XMMU J173203-344518. Since it is expected that heating, accretion or magnetic fields do not play a role for this object, its high temperature is inconsistent with the existence of a neutron superfluid in the star’s core. This motivates the choice of a zero \(P\)-wave gap in our study. (c) Once d\'Urca processes are allowed the cooling rate accelerates strongly; the temperatures of the models are then determined by the interplay of several factors: (i) existence of non-superfluid shells within the stars; (ii) effectiveness of suppression of the d\'Urca process by pairing gaps. The strength of the suppression depends on the magnitude and distribution of the gaps in the star.

Let us now turn to a more detailed discussion of the cooling tracks in Figure 7 for stellar models based on the DDME2 and SWL EOSs. Table 3 provides additional information on the reactions which are dominant in a star with a given mass. It also shows the effectiveness of high-density \(P\)-wave pairing of protons and \(\Lambda\)’s in slowing down the cooling. For DDME2 EOS it is seen that, with the exception of the lightest (1\(M_\odot\)) star, all stars cool through the hyperonic d\'Urca processes and the PBF process in neutron \(S\) - and \(P\)-wave superfluids. (We recall that for the DDME2 EOS the proton fraction is below the nucleonic d\'Urca threshold so that the d\'Urca process does not occur in any of these mass models.) Our calculations allow us to extract the density ranges of various processes: (\(\Lambda, p\)) channel is active in the density range 0.34 \(\leq n_B \leq 1.02\) fm\(^{-3}\) (\(M/M_\odot \geq 1.38\)); the \((\Xi^-, \Lambda)\) channel is active in the range 0.37 \(\leq n_B \leq 0.98\) fm\(^{-3}\) (\(M/M_\odot \geq 1.54\)); the \((\Sigma^-, \Lambda)\) channel is active in the range 0.39 \(\leq n_B \leq 0.60\) fm\(^{-3}\) (1.60 \(\leq M/M_\odot \leq 2\)). Note that here and in all models that will be discussed below the \((\Sigma^-, \nu)\) channel is energetically forbidden. This is not surprising given the large difference in their abundances.

We observe that the mass range 1 \(\leq M/M_\odot \leq 1.85\) covers the observed range of temperature well, showing a clear mass hierarchy of the cooling behavior of NSs in the neutron cooling era \(t \leq 10^3\) yr. [Note that this hierarchy is inverted at the very early \((t \leq 10\) yr\) stages of thermal evolution, which is however observationally insignificant].

\(MNRAS 000, 1-77 (0000)\)
Firstly, we note that switching on and off the neutron P-wave pairing has an important effect on the cooling of low-to-intermediate mass stars as this pairing significantly reduces the heat capacity of the core and induces one of the dominant cooling processes via PBF. For the late cooling era \( t \geq 10^5 \) yr, we find that the cooling tracks computed for zero neutron P-wave pairing gaps are in better agreement with the data than the cooling tracks computed for non-zero gaps. [Note that the youngest stars such as the compact central objects (CCO) in Cass A with an estimated age of \( t \sim 330 \) yr or XMMU J173203.3-344518 with \( t \sim 2.7 \times 10^3 \) yr may have light elements in their atmospheres. Therefore, they may have higher temperatures than predicted by our models.] As can be seen from Table 3, the hyperonic dUrca processes operate in all \( M/M_\odot \geq 1.38 \) stars. Stars with \( 1.40 \leq M/M_\odot \leq 1.6 \) cool down via \((\Lambda, p)\), which is the only active dUrca process in their interiors. In contrast to this, several reactions are triggered in stars with masses of \( M/M_\odot \geq 1.7 \), with \((\Sigma^-, \Lambda)\) being the dominant one. Nevertheless, the cooling of stars with \( M/M_\odot \leq 1.85 \) is not fast because of the presence of a proton and/or \( \Lambda \) superfluidity.

Increasing the mass of the star increases its central density. For a sufficiently massive star, its central density can exceed the density at which the \( \Lambda \) S-wave gap disappears. In this case the stars cool fast by the \((\Sigma^-, \Lambda)\) dUrca processes because at high densities \( \Lambda \)’s are unpaired. However, if one allows for a higher P-wave pairing of \( \Lambda \)’s, it slows down the cooling of the \( M/M_\odot = 2 \) model, as seen Fig. 7. The \( \Lambda \) P-wave pairing scaled from neutron P-wave pairing results of Ding et al. (2016) (right panel) is less effective than the one obtained from that of Baldo et al. (1998) (left panel). The reason is that the latter spans a wider range of densities and its maximum is located at a larger value (see Fig. 4).

Next, we consider the cooling tracks computed for the SWL EoS. They are shown in the lower part of Fig. 7. This case is similar to DDME2 considered above, as the nucleonic dUrca process does not occur in stars with masses \( M/M_\odot \leq 2 \). From our models the density ranges of hyperonic dUrca processes are as follows: \((\Lambda, p)\) channel operates in the density range \( 0.41 \leq n_B \leq 0.94 \text{ fm}^{-3} \) \((1.5 \leq M/M_\odot \leq 2)\), \((\Sigma^-, \Lambda)\) operates in the range \( 0.45 \leq n_B \leq 0.94 \text{ fm}^{-3} \) \((1.66 \leq M/M_\odot \leq 2)\). As was the case for the DDME2 EoS keeping or switching off the P-wave pairing of neutrons affects the cooling of low-to-intermediate mass stars due to the presence or absence of the corresponding PBF process. It can be seen that the zero gap case reproduces the measured surface temperatures of mature \( t \geq 10^7 \) NSs. Because hyperonic dUrca processes are dominant in stars with masses \( M/M_\odot \geq 1.6 \) (see Table 3) the cooling tracks of stars with masses below this value are practically indistinguishable from each other and produce the highest temperatures. Once the hyperonic dUrca processes set in there is a mild drop in the cooling tracks of stars of masses \( M/M_\odot \leq 1.8 \), produced by the balance between the large neutrino emissivities of these hyperonic dUrca processes and the suppression via hyperon and proton S-wave pairing. The onset of the reaction \((\Sigma^-, \Lambda)\), which is only partially suppressed, accelerates the cooling of the most massive stars, leading to a significant drop in their temperature. P-wave pairing of \( \Lambda \)’s results in higher temperatures of stars with \( M/M_\odot \geq 1.9 \), for it diminishes the emissivity of both \((\Sigma^-, \Lambda)\) and \((\Lambda, p)\). Contrary to what we have seen for the case DDME2 EoS based on the P-wave pairing, models, for the SWL EoS based models the P-wave pairing of protons plays a role too when the proton gap is large enough, as it happens when the gap is obtained from scaling the neutron P-wave pairing gap of Baldo et al. (1998). This case is not illustrated in Fig. 7 as it is similar to the case of \( \Lambda \)-P wave pairing.
Figure 7. Cooling models based on the DDME2 EoS (upper two rows) and SWL EoS (lower two rows) for NS masses within the range \(1 \leq M/M_\odot \leq 2\). The left panels use for the triplet of neutron \(^1S_0\) and \(^3P_2-^3F_2\) and proton \(^1S_0\) gaps of/associated with SFB-0-CCDK, where SFB refers to Schwenk et al. (2003) and CCDK to Chen et al. (1993), and \(0\) indicates that the neutron \(P\)-wave pairing gap is zero. The right panels use the DingS-DingP-CCDK triplet. The \(\Lambda\) \(^1S_0\) pairing gaps are based on our BCS computations. The \(\Lambda\) and proton \(P\)-wave gaps are obtained from the scaling procedure described in the text using for the neutron \(P\)-wave the results of Baldo et al. (1998) (left column) and, respectively, Ding et al. (2016) (right column).
Table 3. List of reactions which dominate the cooling evolution (columns 2 and 5) and efficiency of high density pairing of protons and Λs (indicated by − (zero efficiency) or √ (non-zero efficiency) in columns 3, 4, 6, 7) in NS models of various masses built upon EoS which do not allow for nucleonic dUrca, DDME2 (upper part) and SWL (lower part), for any of the considered masses. Columns 2-4 (5-7) correspond to the set SFB-0-CCDK (DingS-DingP-CCDK) for neutron and proton gaps, see text. The Λ \( ^1S_0 \) gaps are based on our BCS computations assuming a background given by the corresponding EoS. The proton and Λ \( ^3P_2 \) gaps are obtained by scaling the neutron \( ^3P_2 \) gap by Baldo et al. (1998) (columns 3-4) or, alternatively, by Ding et al. (2016) (columns 6-7). The abbreviations are as follows: PBF stands for Cooper pair breaking-formation processes; n\( (^3P_2) \) neutron \( ^3P_2 \)-wave pairing and similarly for other baryons and channels. Baryons in brackets, such as (Λ, p) stand for direct Urca process involving indicated baryons [see Eqs. (3)-(6)]. N bremstr. stands for nucleonic bremsstrahlung.

Figure 8. Cooling models based on the PKA1 EoS (upper two rows) and PKO3 EoS (lower two rows) for NS masses within the range $1 \leq M/M_\odot \leq 2$. The left panels use for the triplet of neutron $^1S_0$ and $^3P_2-^3F_2$ and proton $^3S_0$ gaps of/associated with SFB-0-CCDK, where the acronyms SFB refers to Schwenk et al. (2003) and CCDK to Chen et al. (1993), and 0 stands for zero pairing gap. The right panels use the following triplet of pairing gaps: DingS-DingP-CCDK, where DingS and DingP refer to the $^1S_0$ and $^3P_2-^3F_2$ gaps obtained by Ding et al. (2016). The $^1S_0$ pairing gap are based on our BCS computations. The $\Lambda$ and proton $P$-wave gaps are obtained from the scaling procedure described in the text using for the neutron $P$-wave the results of Baldo et al. (1998) (left column) and, respectively, Ding et al. (2016) (right column).
The cooling tracks for the PKA1 and PKO3 EoS are shown in Fig. 8. Compared to the DDME2 and SWL based models discussed above, the new qualitative feature is the low threshold for the nucleonic direct Urca process.

We extract from our PKA1 EoS a density threshold of $n_B \geq 0.25 \text{ fm}^{-3}$ above which the $(n, p)$ reaction is effective. This density corresponds to $M/M_\odot \geq 0.98$, which means that all models considered allow for nucleonic dUrca. Additional contributions come from the hyperonic dUrca processes, where $(\Lambda, p)$ is effective over the density range $0.32 \leq n_B \leq 0.95 \text{ fm}^{-3}$ ($1.44 \leq M/M_\odot \leq 1.99$), $(\Sigma^{-}, \Lambda)$ is effective over the range $0.40 \leq n_B \leq 0.47 \text{ fm}^{-3}$ ($1.59 \leq M/M_\odot \leq 1.67$), and $(\Xi^{-}, \Lambda)$ acts over the range $0.45 \leq n_B \leq 0.95 \text{ fm}^{-3}$ ($1.64 \leq M/M_\odot \leq 1.99$). The cooling tracks, illustrated in the top panels of Fig. 8, fall into three classes. The first class is represented by the lightest star. With a core that accommodates nucleonic dUrca over a volume of insignificant size, the $M/M_\odot = 1$ model manifests slow cooling, via neutrino emission from nucleon bremsstrahlung and PBF from neutron pairing in S- and P-channels. The second class of models, with $1.3 \leq M/M_\odot \leq 1.6$, cool down exclusively or predominantly by the nucleonic dUrca process. As at least one of the involved species, i.e., protons, as or - as in the case for the panels on the right - neutrons, is paired, the cooling is moderate and the cooling tracks cover a domain in the $t$-$T_{\text{eff}}$ plane where observed data exist or are not far from them. The third class is represented by models with $M/M_\odot \geq 1.7$. Their fast cooling is due to unpaired baryons, protons (left panels of Fig. 8) and $\Lambda$s (right panels of Fig. 8). As already discussed in relation with the DDME2- and SWL-models, even a small neutron $P$-wave pairing leads to accelerated cooling for $t \gtrsim 10^8 \text{ yr}$, irrespective of the star’s mass. According to Table 4, even a tiny neutron $P$-wave pairing gap (or, equivalently $T_{\text{eff}}$) as the one of Ding et al. (2016) is sufficient to switch the dominant dUrca from nucleonic (left panels, no neutron $P$-pairing) to hyperonic (right panels, with neutron $P$-pairing).

Switching on and off the $P$-wave superfluidity in the proton and $\Lambda$ components does not change the general behavior of cooling tracks qualitatively. It is seen that most massive stars with $P$-wave superfluidity have higher temperatures compared to their counterparts without such pairing. Depending on whether or not neutron $P$-wave pairing occurs, the cooling of these stars is slowed down by proton- or, alternatively, $P$-$P$-wave pairing.

The models based on the PKO3 EoS, shown in the bottom panels of Fig. 8, are qualitatively similar to those based on the PKA1 EoS. The reason for this lies in the relatively low nucleonic dUrca threshold, $n_B \geq 0.28 \text{ fm}^{-3}$, which makes this channel effective in models with $M/M_\odot \geq 1.22$. The $(\Lambda, p)$ and $(\Xi^{-}, \Lambda)$ hyperonic dUrca processes act over baryonic density ranges of $0.33 \leq n_B \leq 0.86 \text{ fm}^{-3}$ and $0.54 \leq n_B \leq 0.83 \text{ fm}^{-3}$, respectively, which correspond to NS masses domains of $1.56 \leq M/M_\odot \leq 1.99$ and $1.89 \leq M/M_\odot \leq 1.99$.

As for PKA1 EoS based models, the nucleonic dUrca in stars with $M/M_\odot \geq 1.8$ is suppressed by the neutron $P$-wave pairing; as a consequence, the hyperonic dUrca, in this case $(\Lambda, p)$, is as efficient as the nucleonic dUrca. As illustrated in Fig. 1, PKO3 EoS leads to lower proton- and $\Lambda$-abundances than PKA1 EoS. As a consequence, the $^1S_0$-pairing of protons and $\Lambda$’s computed for stellar models based on the PKO3 EoS extends over larger core regions than is the case for models based on the PKA1 EoS. They are additionally characterized by higher critical temperatures, as can be seen in Figs. 5 and 6. These facts explain the quantitative differences between the cooling curves associated with the two EoS. The separation between slow-, intermediate- and fast-cooling tracks is less pronounced for PKO3 than for PKA1 based EoS. We also note that for a given stellar mass and fixed set of pairing-gaps, the effective temperatures are higher. The lower densities of protons and $\Lambda$’s produced by PKO3 render the high-density pairing of these particles less efficient. Indeed, the drop in the temperature becomes smaller only for models with $M/M_\odot = 1.9$ and 2 when $P$-wave pairing is additionally taken into account; this occurs only for $M/M_\odot = 2$ models if proton $P$-wave pairing is included in addition.

4 CONCLUSIONS

This work extends the previous study of Raduta et al. (2018) to the cooling of hypernuclear stars by including models for the EoS based on the Hartree-Fock treatment of the hypernuclear matter. We conjecture on the existence of new channels of $P$-wave pairing in the proton and $\Lambda$ components of our models and explore their effect on the cooling behavior of NSs using simple scaling relations for the pairing gaps. The EoS models can be classified into two groups: the first group, which includes the DDME2 and SWL models, has a low-$L$ value and no not allow for nucleonic dUrca or allow for it only in very massive stars. The second group consists of GM1A and all HF models, which have a high $L$ value but a rather low nucleonic dUrca threshold.

• Mass hierarchies and observational data. We find in general that all the models follow a mass-hierarchy. If one arranges the stars from the lightest to the heaviest ones, the former cool always slower than the latter in the neutrino cooling era $t < 10^5 \text{ yr}$. This hierarchy may be inverted at a very early stage of evolution, i.e., the heavier stars may cool slower than the lighter stars. Similar inversion also is observed at very late stages, when the cooling is dominated by photon emission from the stellar surface (photon cooling era). For the DDME2 and SWL EoS based models, we find that they smoothly cover the observationally relevant area in the $t$-$T_{\text{eff}}$ diagram. Interestingly, we find that vanishing $P$-wave neutron superfluidity improves the agreement with the observational data for our hypernuclear models, a feature already observed in alternative models of cooling evolution of NS. The Hartree-Fock models develop nucleonic dUrca processes rather early. This results in a very fast cooling of these models which renders the agreement with the data difficult. Nevertheless, for the PKO3 model, we find that light to medium-mass stars have cooling tracks that pass through the observationally relevant region in the $t$-$T_{\text{eff}}$ diagram.

• High-density pairing. In this part of the work, we attempted to rectify the too rapid cooling of the most massive NS models of our study, which is linked to the closing of the $^1S_0$ gaps for $\Lambda$’s and protons at high densities. We have proposed simple scaling arguments for obtaining the gaps of these particles from those computed for neutron matter. From this, we found that if $P$-wave pairing of protons and $\Lambda$’s is allowed, then even the most massive
(1.9 ≤ M/M⊙ ≤ 2) hypernuclear stars will undergo a significantly slower cooling evolution.

The diversity among presently considered hypernuclear EoSs, which leads to differences in the thermal evolution of NSs, is partly rooted in the uncertainties in the nucleonic sector (L-value and, very probably, higher order terms of the expansion of the symmetry energy as a function of scalar density), the assumed spin-flavor symmetry of the quark model which controls the coupling of hyperons to nucleons in the vector meson sector, and the uncertainty in the values of the hyperon-nucleon interaction potential which does the same in the scalar meson sector. An interesting possibility not studied so far is a lower value of Σ potential in the nuclear matter than assumed here. In that case, already relatively light mass stars will experience fast cooling via Σ− → Λ + l + νl, even if Λ-pairing is taken into account.

For DDME2 our preliminary results show that models with M/M⊙ ≥ 1.5 manifest strong disagreement with the data. The situation might nevertheless significantly improve if one additionally allows for Σ-pairing. These scenarios are under consideration and will be published elsewhere. Despite of this diversity, our study elucidates how various ingredients of microphysical input (parametrisation of the EoS, pairing gaps, etc.) affect the cooling evolution of neutron stars. This establishes controlled correspondence between various input parameters and the general behavior of cooling tracks of hypernuclear stars, which can be used as a diagnostics of the internal composition of NSs in the future.
