HOW SHOULD ONE DEFINE ENTROPY PRODUCTION FOR NONEQUILIBRIUM QUANTUM SPIN SYSTEMS?

by David Ruelle*.

Abstract. This paper discusses entropy production in nonequilibrium steady states for infinite quantum spin systems. Rigorous results have been obtained recently in this area, but a physical discussion shows that some questions of principle remain to be clarified.

Keywords: statistical mechanics, nonequilibrium, entropy production, quantum spin systems, reservoirs.

* IHES. 91440 Bures sur Yvette, France. <ruelle@ihes.fr>
1. Introduction.

Recent papers by Ruelle [4], [5], and Jakšić and Pillet [3] have discussed the nonequilibrium statistical mechanics of infinite quantum spin systems, and in particular the positivity of entropy production. Mathematically, these papers are based on the treasure of results accumulated in the two volumes of *Operator algebras and quantum statistical mechanics* by Bratteli and Robinson [2]. In particular the concepts of relative modular operator and relative entropy, developed by Huzihiro Araki [1], turn out to play an essential role (see [3]). Clearly, the current surge of activity in nonequilibrium statistical mechanics is going to make more demands on operator algebras, and on the basic structural facts discovered about these algebras by Tomita, Takesaki, and Araki. The present paper is however less concerned with mathematics than with the physical question of how to define entropy production. We shall try to find out what is likely to be true or not true in this area, and therefore what are the theorems that one should attempt at proving.

2. A formula for the entropy production in a finite system.

In this section we consider a finite system described by a density matrix $\psi$ on a finite-dimensional Hilbert space $\mathcal{H}$. The (von Neumann) entropy associated with $\psi$ is

$$S(\psi) = -\text{Tr} \psi \log \psi$$

In the presence of a time evolution defined by unitary operators $U(t)$ on $\mathcal{H}$ we may define

$$\psi(t) = U(t)\psi U(-t)$$

It is clear and well known that the entropy $S(\psi(t))$ is independent of $t$: there is no entropy production in this setup. To understand entropy production we have to think of a large system (the universe) of which we observe a small part. By virtue of the time evolution, there are correlations between the state of the small system, and parts of the large system that are more and more remote. After a while these correlations are forgotten, or equivalently entropy is created. This is basically the way entropy production was understood by Boltzmann.

We shall follow this way of thinking, and consider that our system is composed of several subsystems labelled by an index $a = 0, 1, \ldots$ Correspondingly $\mathcal{H} = \bigotimes_{a \geq 0} \mathcal{H}_a$, we assume that the $U(t)$ form a one-paramameter group of unitary transformations of $\mathcal{H}$, with $U(t) = e^{-iHt}$.

We can now define a density matrix $\psi_a(t)$ on $\mathcal{H}_a$ as a partial trace:

$$\psi_a(t) = \text{Tr}_{\mathcal{H}\backslash a} \psi(t)$$

where $\mathcal{H}\backslash a = \bigotimes_{b \neq a} \mathcal{H}_b$. The entropies

$$S_a(t) = -\text{Tr}_{\mathcal{H}_a} \psi_a(t) \log \psi_a(t)$$
may depend on \( t \), and we define the (rate of) entropy production \( e = e(t) \) as

\[
e = \frac{d}{dt} \sum_{a \geq 0} S_a(t) = \frac{d}{dt} \left( \sum_{a \geq 0} S_a(t) - S(\psi(t)) \right)
\]

This is the rate of change of entropy associated with the decomposition of the system described by \( \psi(t) \) into the subsystems described by \( \psi_a(t), \ a \geq 0 \).

Note that by the subadditivity of the entropy

\[
\sum_{a \geq 0} S_a(t) - S(\psi(t)) \geq 0
\]

This positive quantity may be viewed as the information lost about the state \( \psi(t) \) of the system when we cut it into the subsystems labelled by \( a = 0, 1, \ldots \). In the large system limit where correlations move away and disappear at infinity, we expect \( \sum_{a \geq 0} S_a(t) - S(\psi(t)) \) to be an increasing function of \( t \), so that \( e \geq 0 \) (at least in the average). But for the moment we consider finite systems, \( i.e. \), we keep \( \mathcal{H} \) finite dimensional, and we look more carefully at the expression for the entropy production.

Let us write

\[
H = \sum_{a \geq 0} H_a + h
\]

where

\[
H_a = 1 \otimes \hat{H}_a
\]

and \( 1 \otimes a \) is the unit operator on \( \mathcal{H}_a \). (Note that that the choice of \( h, \hat{H}_a \) is not unique, one may in particular take \( h = H \) and all \( H_a = 0 \)). Then, to first order in \( dt \),

\[
\psi(t + dt) = e^{-iHdt}\psi(t)e^{iHdt} = \psi(t) - i dt[H, \psi(t)] = \psi(t) - i dt[\sum_{a \geq 0} H_a + h, \psi(t)]
\]

hence

\[
\psi_a(t + dt) = \psi_a(t) - i dt[\hat{H}_a, \psi_a(t)] - i dt\text{Tr}_{\mathcal{H}_a}[h, \psi(t)]
\]

Therefore, assuming that \( \psi(t) \) is invertible so that the log is well defined,

\[
S_a(t + dt) = -\text{Tr}_{\mathcal{H}_a} \psi_a(t + dt) \log \psi_a(t + dt)
\]

\[
= \sigma_1 + \sigma_2
\]

where

\[
\sigma_1 = -\text{Tr}_{\mathcal{H}_a} \psi_a(t) \log (\psi_a(t) - i dt[\hat{H}_a, \psi_a(t)] - i dt\text{Tr}_{\mathcal{H}_a}[h, \psi(t)])
\]

\[
= -\text{Tr}_{\mathcal{H}_a} \psi_a(t) \log \psi_a(t) + i dt\text{Tr}_{\mathcal{H}_a}[\hat{H}_a, \psi_a(t)] + i dt\text{Tr}_{\mathcal{H}_a}\text{Tr}_{\mathcal{H}_a}[h, \psi(t)]
\]

\[
= -\text{Tr}_{\mathcal{H}_a} \psi_a(t) \log \psi_a(t)
\]
\[
\sigma_2 = i \, dt \text{Tr}_{\mathcal{H}_a}(\{\hat{H}_a, \psi_a(t)\}) + \text{Tr}_{\mathcal{H} \setminus a}[h, \psi(t)] \log \psi_a(t)
\]
\[
= i \, dt \text{Tr}_{\mathcal{H}_a}(\text{Tr}_{\mathcal{H} \setminus a}[h, \psi(t)]) \log \psi_a(t) = i \, dt \text{Tr}_{\mathcal{H}}([h, \psi(t)](1 \otimes \log \psi_a(t)))
\]
\[
= -i \, dt \text{Tr}_{\mathcal{H}}(\psi(t)[h, 1 \otimes \log \psi_a(t)])
\]

Therefore
\[
S_a(t + dt) - S_a(t) = -i \, dt \text{Tr}_{\mathcal{H}}(\psi(t)[h, 1 \otimes \log \psi_a(t)])
\]

and finally
\[
e = -i \text{Tr}_{\mathcal{H}}(\psi(t)[h, \log \otimes_{a \geq 0} \psi_a(t)])
\]

Note that we may in (1) and (2) replace \(h\) by the total Hamiltonian \(H\) (take all \(\hat{H}_a = 0\)):
\[
e = -i \text{Tr}_{\mathcal{H}}(\psi(t)[H, \log \otimes_{a \geq 0} \psi_a(t)])
\]

3. The large system limit.

We shall be interested in the limit of a large system. More precisely, the subsystem \(R_0 = \Sigma\) corresponding to \(a = 0\) will remain small, but it will interact with reservoirs \(R_1, R_2, \ldots\), which will become large (there is no direct interaction between the reservoirs).

We shall be interested in the case where there are at least two large reservoirs (in the case of only one large reservoir \(R_1\), we expect that the small system \(\Sigma\) will get in equilibrium with \(R_1\) if we wait long enough – this is the situation of approach to equilibrium). We think of the reservoirs \(R_1, R_2, \ldots\) as having different inverse temperatures \(\beta_1, \beta_2, \ldots\). Of course, putting the reservoirs in contact with the small system \(\Sigma\) will produce a flow of heat, so that the temperature in the reservoirs will not remain uniform, in particular the entropy production \(e\) defined by the large system limit of (2) might depend on where the boundary between the small system and the reservoirs is put. [It is also possible that it does not since, physically, entropy production depends on information disappearing at infinity on different sides of some separating surfaces, and the exact position of these surfaces may not be important]. In any case we are interested in a double limit where first the reservoirs are allowed to become infinite and then, perhaps, the boundaries between the small system and the reservoirs are allowed to move to infinity. This double limit is more or less imposed by physics, but seems hard to analyze mathematically. Note for example that we expect the entropy \(-\text{Tr}(\psi \log \otimes_{a \geq 0} \psi_a) + \text{constant}\) to diverge in a large system limit where it becomes time independent while its time derivative tends to a nonzero constant \(e\).

We shall try to argue that in the double limit discussed above, (2) becomes the standard thermodynamic relation between the heat fluxes and the temperatures of the reservoirs, but we shall not be able to give a proof of this fact. Basically, our difficulty is to make sense of the limit of \(\log \otimes_{a \geq 0} \psi_a\) or \([h, \log \otimes_{a \geq 0} \psi_a]\).

4. Infinite systems.

In order to be able to discuss a small system \(\Sigma\) coupled with actually infinite reservoirs \(R_a\) with \(a > 0\), we shall now introduce more structure into the problem. Let \(L\) be countably
$\mathcal{H}_x$ be a finite dimensional Hilbert space for each $x \in L$. We let $L$ be the disjoint union $L = \bigcup_{a \geq 0} R_a$, where $R_0 = \Sigma$ is finite and the $R_a$ with $a > 0$ are infinite. Choosing $\Lambda$ finite such that $\Sigma \subset \Lambda \subset L$, we may define $\mathcal{H}_a = \mathcal{H}_{\Lambda a} = \bigotimes_{x \in \Lambda \cap R_a} \mathcal{H}_x$, $\mathcal{H} = \mathcal{H}_{\Lambda} = \bigotimes_{x \in \Lambda} \mathcal{H}_x$, and study the finite system defined by a density matrix $\psi(t) = \psi_{\Lambda}(t)$ on $\mathcal{H}_{\Lambda}$ and a (self-adjoint) Hamiltonian $H = H_{\Lambda}$ on $\mathcal{H}_{\Lambda}$.

For finite $X \subset L$ let $A_X$ be the $C^*$-algebra of operators on $\mathcal{H}_X = \bigotimes_{x \in X} \mathcal{H}_x$. If $Y \subset X$ we may identify $A_Y$ with a subalgebra of $A_X$ by $B \mapsto B \otimes 1_{X \setminus Y}$, and define the quasilocal $C^*$-algebra $A$ corresponding to $L$ as the norm closure of $\bigcup_X A_X$. We can then introduce a Hamiltonian for the infinite system $L$ as the formal expression

$$H^\Phi_L = \sum_{X \subset L} \Phi(X)$$

where the sum is over finite subsets $X$ of $L$, and $\Phi(X)$ is self-adjoint $\in A_X$. The finite system Hamiltonian is then defined by*

$$H = H^\Phi_{\Lambda} = \sum_{X \subset \Lambda} \Phi(X)$$

The infinite system limit consists now in letting $\Lambda$ tend to infinity in a suitable way, which we shall not discuss (but $\Lambda$ should eventually contain any given finite set). We may assume that the density matrices $\psi_{\Lambda}(t)$ tend to a time independent state $\rho$ on $A$ when $\Lambda \rightarrow L$ in the sense that

$$\text{Tr}_{\mathcal{H}_{\Lambda}} \psi_{\Lambda}(t) A \rightarrow \rho(A) \quad \text{if} \quad A \in A_X$$

for finite $X \subset L$. We want to take for $\rho$ not just a time invariant state, but one which qualifies as nonequilibrium steady state (so that in particular, if the entropy production can be defined, it is not negative). We shall discuss nonequilibrium steady states below.

Of the quantities occurring in (1) and (2) we see that we can now replace $\text{Tr}_{\mathcal{H}}(\psi(t) \cdots)$ by $\rho(\cdots)$. For finite range interactions, $h$ is a well defined element of $A$ and independent of $\Lambda$ for sufficiently large $\Lambda$. The operator $H$ is, in the limit of infinite $\Lambda$ given formally by $H^\Phi_L$ as defined above.

It is however not clear what to do with the limit of $\log \otimes_{a \geq 0} \psi_a(t)$. One idea would be to assume that

$$\log \psi_{\Lambda}(t) + c_{\Lambda} 1_{\Lambda} \rightarrow - \sum_{X \subset L} \Phi(X)$$

where the $c_{\Lambda}$ are constants and the right hand side is (up to sign) a formal sum of self-adjoint elements $\Phi(X) \in A_X$ for finite $X \subset L$. But such an Ansatz conflicts with the notion that $\log \psi_{a}(t)$ for a reservoir has long distance correlations, i.e., very large or infinite sets $X$ should be important in the the formula displayed above. In conclusion, we believe, for

* This may be modified (for instance by boundary terms) provided formally $H_{\Lambda} \rightarrow H_L$ when $\Lambda$ tends to $L$.  

5
physical reasons that the infinite system limit of the entropy production makes sense, but
we cannot prove this fact.

5. The thermodynamic formula for the entropy production.

At this point we have come to an expression of \( e \) as limit when \( \Lambda \) tend to infinity (or \( \Lambda \rightarrow L \)) of

\[
-i \text{Tr}(\rho_\Lambda[H^\Phi_\Lambda, \log \otimes_{a \geq 0} \psi_a]) = i \text{Tr}([H^\Phi_\Lambda, \rho_\Lambda] \log \otimes_{a \geq 0} \psi_a)
\]

Since \( \rho \) is invariant under the time evolution defined by \( H^\Phi_\Lambda \), we have \( \rho([H^\Phi_\Lambda, A] = 0 \) if \( A \) belongs to a local algebra and \( \Lambda \) is sufficiently large. Therefore, \( \text{Tr}([H^\Phi_\Lambda, \rho_\Lambda] A) \) vanishes if \( A \) is localized well inside \( \Lambda \), and is nonzero only for \( A \) localized near the boundary of \( \Lambda \). In other words, in computing \( e \) we may ignore local terms from \( \log \otimes_{a \geq 0} \psi_a \) and pay attention only to contributions from far away, at the boundary of \( \Lambda \). An obvious guess is then to replace \( \psi_a \) by the equilibrium state at temperature \( \beta_a \) in \( R_a \), obtaining now \( e \) as limit when \( \Lambda \rightarrow L \) of

\[
i \text{Tr}(\rho_\Lambda[H^\Phi_\Lambda, \sum_a \beta_a H^\Phi_\Lambda \cap R_a]) = i \rho(\sum_a \beta_a [H^\Phi_\Lambda, H^\Phi_\Lambda \cap R_a])
\]

Note that \( \lim_{\Lambda \rightarrow L} i[H^\Phi_\Lambda, H^\Phi_\Lambda \cap R_a] \) is a well defined operator localized near the surface of the small system \( \Sigma \); it represents the rate of transfer of energy to the reservoir \( R_a \) and therefore for large enough \( \Lambda \)

\[
e = \rho(\sum_a \beta_a i[H_a, H_\Lambda \cap R_a])
\] (3)

In fact (3) is the usual thermodynamic expression of the entropy production in terms of heat fluxes. Note that we may ignore the term with \( a = 0 \) since the fluxes to the small system add up to 0 in a stationary state.

We shall from now on proceed with the formula (3) for the entropy production, but remember that its relation with (2) has not been satisfactorily established.

6. Nonequilibrium steady states (NESS).

The definition of nonequilibrium steady states (NESS) should choose a direction of time, i.e., distinguish between the past and the future. Otherwise one cannot hope to prove that the entropy production \( e \) has a definite sign. One must also impose the asymptotic temperatures \( \beta_1, \beta_2, \ldots \) in the reservoirs \( R_1, R_2, \ldots \) We assume that the interaction \( \Phi \) determines a one-parameter group \((\alpha^t)\) of automorphisms of \( \mathcal{A} \), defining the time evolution of our system (see [2]). Let \( \sigma_1, \sigma_2, \ldots \) be equilibrium states at inverse temperature \( \beta_1, \beta_2, \ldots \) for the reservoirs \( R_1, R_2, \ldots \) and \( \sigma_0 \) any state for the small system \( \Sigma = R_0 \). Assuming the existence for each \( A \in \mathcal{A} \) of a limit

\[
\lim_{t \rightarrow \infty} (\otimes_{a \geq 0} \sigma_a)(\alpha^t A) = \rho(A)
\] (4)

defines a state \( \rho \) which one can certainly call a NESS. One can prove the existence of the limits (4) under strong conditions of asymptotic abelianness in time of the evolution \( (\alpha^t) \)
and also of the “uncoupled” evolutions ($\dot{\alpha}_t$). This was the point of view adopted in [4]. It has the advantage of leading to strong results like linear response formulae, but the disadvantage that the assumed asymptotic abelianness can practically never be verified. Progress in understanding nonequilibrium quantum spin systems will probably depend on a better understanding of the asymptotic abelianness conditions in question.

It is however possible to obtain some results without unverifiable assumptions by considering limit points for $T \to \infty$ of

$$\frac{1}{T} \int_{0}^{T} dt (\alpha^t)^* (\otimes_{a \geq 0} \sigma_a)$$

in the weak dual of $\mathcal{A}$. Such limit points $\rho$ always exist (by $w^*$-compactness of the set of states) and they are invariant under time evolution. The limit points $\rho$ are good candidates to represent nonequilibrium steady states. In fact, it has been proved in [5], and more generally in [3] that the entropy production $e$ defined by (3) is $\geq 0$ for such states. [The reason is basically that the commutator in (3) is a derivative, which combines with the integral in (5) to produce a manageable expression].

If one assumes that the $\sigma_a (a > 0)$ are extremal KMS states and that $(\alpha^t)$ is asymptotically abelian one can show (see [5]) that the definition of the NESS as limit points of (5) does not depend on where the boundaries between the small system $\Sigma$ and the reservoirs $R_a (a > 0)$ are placed. This is of course quite desirable. Asymptotic abelianness of $(\alpha^t)$ also ensures that the NESS have a unique ergodic decomposition. So, even with the definition of NESS based on (5), questions of asymptotic abelianness seem to appear unavoidably. This is natural because if our system is composed of subsystems that do not interact (say the small system does not interact with the reservoirs, we violate asymptotic abelianness, and have an uninteresting theory.

We have said nothing of the geometry of the reservoirs $R_a (a > 0)$, but consideration of the macroscopic limit shows that (if they are pieces of regular lattices $\mathbb{Z}^d$) their dimension $d$ must be $\geq 3$. Indeed in the macroscopic limit, a NESS corresponds to a temperature field $T$ satisfying $\Delta T = 0$ (say), and tending to limits $\beta_a^{-1}$ in the various reservoirs. In view of properties of harmonic functions this cannot happen for $d < 3$. What will happen for $d < 3$ is that the temperature will tend, as time goes to infinity, to a constant in any bounded region, the temperature gradient and heat flux will tend to zero, and the NESS will reduce to a thermodynamic equilibrium state with $e = 0$.

In conclusion we hope to have shown in this note that, on our way to understanding quantum nonequilibrium statistical mechanics, there remains not only problems of mathematics to solve but also questions of physics to clarify.
