Abstract

The presence of oligoclonal bands (OCB) in cerebrospinal fluid (CSF) is a typical finding in multiple sclerosis (MS). We applied data from Norwegian, Swedish and Danish (i.e. Scandinavian) MS patients from a genome-wide association study (GWAS) to search for genetic differences in MS relating to OCB status. GWAS data was compared in 1367 OCB positive and 161 OCB negative Scandinavian MS patients, and nine of the most associated SNPs were genotyped for replication in 3403 Scandinavian MS patients. HLA-DRB1 genotypes were analyzed in a subset of the OCB positive (n = 2781) and OCB negative (n = 292) MS patients and compared to 890 healthy controls. Results from the genome-wide analyses showed that single nucleotide polymorphisms (SNPs) from the HLA complex and six other loci were associated to OCB status. In SNPs selected for replication, combined analyses showed genome-wide significant association for two SNPs in the HLA complex; rs3129871 (p = 5.7 × 10^{-15}) and rs3817963 (p = 5.7 × 10^{-15}) correlating with the HLA-DRB1*15 and the HLA-DRB1*04 alleles, respectively. We also found suggestive association to one SNP in the Calsyntenin-2 gene (p = 8.83 × 10^{-7}). In HLA-DRB1 analyses HLA-DRB1*15:01 was a stronger risk factor for OCB positive than OCB negative MS, whereas HLA-DRB1*04:04 was associated with increased risk of OCB negative MS and reduced risk of OCB positive MS. Protective effects of HLA-DRB1*01:01 and HLA-DRB1*07:01 were detected in both groups. The groups were different with regard to age at onset (AAO), MS outcome measures and gender. This study confirms both shared and distinct genetic risk for MS subtypes in the Scandinavian population defined by OCB status and indicates different clinical characteristics between the groups. This suggests differences in disease mechanisms between OCB negative and OCB positive MS with implications for patient management, which need to be further studied.

Introduction

Multiple sclerosis (MS) is an inflammatory disorder of the central nervous system leading to demyelination and axonal damage. The cause of MS is unknown, but studies support a multifactorial etiology [1]. The association of MS to genes in the major histocompatibility complex (MHC) was early established [2], and carriers of the HLA-DRB1*15:01 allele have more than three times increased risk for the disease [3]. In recent years, genome-wide association studies (GWAS) have identified more than 50 additional non-HLA loci associated with MS susceptibility.
Patients and Controls

The screening phase initially included 1574 MS patients collected in Norway (n = 899), Denmark (n = 244) and Sweden (n = 431). In the replication phase, 3568 additional samples from Norway (n = 1236), Sweden (n = 1390) and Denmark (n = 942) underwent genotyping. All MS patients were diagnosed in accordance with the Poser and/or McDonald criteria [5,6]. The analyses further included 428 Swedish healthy controls from the EIMS study [20] and 890 healthy controls from the Norwegian bone marrow donor registry.

CSF Analyses

CSF analyses were performed by isoelectric focusing with immunoblotting (IEF), agarose gel electrophoresis (AGE) and/or measures of IgG index (CSF/serum IgG-CSF/serum albumin). A patient was characterized as OCB positive if oligoclonal bands were detected in the CSF by IEF or AGE and/or in the presence of increased IgG index. A patient was described as OCB negative only in the absence of OCB detection on IEF or AGE. Less than 3% of the patients had measures of IgG index only.

Genome-wide SNP Data and SNPs for Replication

In the screening phase genotype data from 580,030 SNPs from the International Multiple Sclerosis Genetics Consortium (IMSGC) and Wellcome Trust Case Control Consortium2 (WTCCC2) GWAS was available for association analyses to OCB status in 1406 OCB positive and 168 OCB negative MS patients and 428 Swedish controls [3]. After quality control, 495,970 SNPs were left for analyses in 1528 patients (1367 OCB positive and 161 negative). All samples were genotyped by the Illumina Human 660-Quad chip performed on the Illumina Infinium platform at the Wellcome Trust Sanger Institute as described previously [3].

Nine of the top hit SNPs identified in the screening phase were selected for replication in accordance with the following criteria: p-value from the screening phase <10^{-5}, level of deviation from HWE p>0.001, minor allele frequency (MAF) >5% (all SNPs but rs11790235 on chromosome 9) and the suitability of the context sequences for design of primers. GWAS cluster plots for all replicated SNPs were inspected specifically for the Scandinavian samples. Two SNPs located in the PRRK1 gene were excluded as their context sequences also aligned to the MS associated gene HLADRB1. All the SNPs in the HNMT gene on chromosome 2 (n = 14) were in high or complete linkage disequilibrium (LD) (r^2 and D*: 0.9-1). We selected three of these SNPs for genotyping from different regions (intron 1 and 3’UTR). The context sequences were obtained from UCSC Genome Browser dbSNP 132, Human Feb. 2009 assembly [http://genome.ucsc.edu/] [21].

Genotyping

The SNPs selected for replication were genotyped by Sequenom technology (San Diego, Ca, USA). Duplicates from the screening (n = 174) and within the replication (n = 120) were genotyped as positive controls. HLADRB1 genotypes of two digit resolution for 405 Norwegian patient samples were available from previous studies [22,23], and four digit HLA typing in the remaining Norwegian patients (n = 1652) and healthy Norwegian controls (n = 890) was performed by a sequence based approach [24]. HLA typing in the Swedish samples was performed as previously described [25]. Of the Swedish samples included in our HLADRB1 genotype analyses, only 18 samples overlapped with the previous study by Imrell et al. [12].

Statistical Analyses

Association testing of OCB status to the clinical parameters gender, AAO, clinical course, MS outcome measures (EDSS and MSSS) was performed by chi square testing (disease course and
and confidence interval (CI) for each associated frequency threshold was set to 5% [27]. The odds ratio (OR) testing was performed in Unphased 03.01.10 where allelic correlation coefficient estimations. association analyses, conditional logistic regression testing and meta-analyses. R 2.12.1 (www.r-project.org) was used in SNP covariate. Combined analyses were performed by fixed effects applying an additive genotype model including AAO as a testing to OCB status was performed by logistic regression analyses (screening) and Breslow Day testing (replication). SNP association testing to OCB status was performed by logistic regression analyses, conditional logistic regression testing and correlation coefficient estimations. HLA-DRB1 allelic association testing was performed in Unphased 03.01.10 where allelic frequency threshold was set to 5% [27]. The odds ratio (OR) and confidence interval (CI) for each associated HLA-DRB1 allele were calculated by specifically testing the risk of the associated allele against all other HLA-DRB1 alleles with frequencies above 5% pooled together.

Results

Genetic Association to OCB Status

Initial analyses of clinical parameters in relation to OCB status revealed nominal association of OCB status to AAO (p = 0.05) (Table 1). Hence AAO was included as a covariate in all subsequent analyses. In the genome-wide screening phase 495,970 SNPs were left for analyses in 1528 patients (1367 OCB positive and 161 negative) after quality control. In subsequent logistic regression analyses, 31 SNPs located in seven different genetic regions, including the MHC, showed a trend for association to OCB status (p<10^{-5}) (Table S1). We found no evidence of population heterogeneity (l = 1) and inclusion of the first four principal components gave comparable results (Table S1).

When genotype frequencies in OCB negative and OCB positive patients were compared to Swedish healthy controls (n = 428) genotyped in the same GWAS [3] (Table S2), nearly all the identified non-HLA SNPs showed association to the OCB negative group only. On the other hand, all but two SNPs in the MHC (rs34083746 and rs3957148) showed significant association only to the OCB positive group. Rs34083746, located within HLA-DRB1, showed association of opposite effects in the OCB positive and OCB negative group only. Rs3957148 near HLA-DQA2 showed association to the OCB negative group only.

In the replication phase, nine of the 31 SNPs were analyzed in 1574 individuals (n = 3029 OCB positive and n = 374 OCB negative) (Table 2). These SNPs were selected in accordance with the criteria described in materials and methods. All SNPs had genotyping call rates above 97% and were in Hardy Weinberg equilibrium (HWE) (p = 0.15). In order to exclude that the deviation from HWE was due to genotyping error, we manually inspected the cluster plots of this SNP to ensure that the deviation from HWE was due to genotyping error. Further, more, there were no missing genotypes in the screening phase and only 1% missing genotypes in the replication phase (32 out of 3403) for rs3817963. Since this genetic region is known to be highly disease associated, and the genotyping results appeared to

Abbreviations: M = Male, F = Female, AAO = Age at onset, PP = Primary progressive, RR = Relapsing remitting, OCB = Oligoclonal bands, EDSS = Expanded Disability Status Scale, MSSS = Multiple Sclerosis Severity Score.

The p values for association between OCB status and the annotated clinical parameters.

Gender, two sample t-tests assuming equal variances (AAO) and Wilcoxon signed rank test (EDSS and MSSS). PLINK software v.1.06 (http://pngu.mgh.harvard.edu/purcell/plink/) [26] was used in quality control. In the screening, individuals with >1% missing genotypes, excess homo-/heterozygosity or who were related (pi hat <0.2) and SNPs with call rates <90% or having failed internal quality control at Sanger were excluded [9]. In the replication, individuals with >1/9 missing genotypes were excluded (n = 165). Population heterogeneity was assessed by principal component plots and genomic inflation factor l (screening) and Breslow Day testing (replication). SNP association testing to OCB status was performed by logistic regression analyses applying an additive genotype model including AAO as a covariate. Combined analyses were performed by fixed effects meta-analyses. R 2.12.1 (www.r-project.org) was used in SNP association analyses, conditional logistic regression testing and correlation coefficient estimations.
be of good quality, a possible explanation for the deviation from HWE is that the genotype data arrived from cases only. Associations to OCB status were replicated for the two SNPs included from the MHC region; rs3817963 (p-value = 6.6 × 10^{-6}, OR = 1.51) and rs3129871 (p-value = 2.8 × 10^{-6}, OR = 1.69). In addition, rs17411949 in the CLSTN2 gene on chromosome 3 showed nominal significant association (p-value = 0.02, OR = 1.47). No other SNP showed association in the replication phase (p > 0.05). Breslow-Day testing showed no significant population heterogeneity, and adjusting for population stratification revealed comparable results (data not shown).

Combining the results from the screening and replication phases, revealed genome-wide significant associations to OCB status for the two HLA-SNPs rs3817963 (p_{combined} = 5.7 × 10^{-10}, OR = 1.61) and rs3129871 (p_{combined} = 5.7 × 10^{-15}, OR = 1.72) and suggestive evidence that rs17411949 in the CLSTN2 gene (p_{combined} = 8.8 × 10^{-7}, OR = 1.85) increases risk of OCB negative MS (Table 2). Combined analysis of the clinical parameters in relation to OCB status (Table 1), showed that the OCB negative patients had significantly lower MSSS (4.05 vs. 4.40, p = 0.02), older AAO (34.2 vs. 33.0, p = 0.01) and were more likely to be male (p = 0.02).

**HLA-DRB1*15:01 and *04:04 are Associated with OCB Status**

In order to investigate for correlation of the associated SNPs in the MHC region to common HLA-DRB1 alleles, we calculated their correlation coefficients to HLA-DRB1 genotypes available in 822 of the 859 Norwegian samples included in the screening phase. All the HLA SNPs showed strongest correlation with either DRB1*15 or DRB1*04 alleles (r = 0.65) (Table 3 and Table S3). We therefore analyzed the association of the HLA-SNPs in the GWAS screened Norwegian samples against, conditioning on the HLA-DRB1*15 and *04 alleles, whereby association of all HLA-SNPs became non-significant (Table 3).

Since our analyses implied that associated HLA-SNPs from the screening likely reflected signals from the HLA-DRB1 *04 and *15 alleles, we performed a third stage of analyses of HLA-DRB1 genotypes in relation to OCB status, HLA-DRB1 genotype data with two digit resolution was available for a subset of the Norwegian (n = 2068) and Swedish MS patients (n = 1005) (including in total 292 OCB negative patients). When comparing HLA-DRB1*15 allele frequencies in OCB negative and OCB positive MS patients, HLA-DRB1*15 conferred relative protection for OCB negative MS (p-value = 1.28 × 10^{-7}, OR = 0.59, 95% CI 0.48–0.73) and HLA-DRB1*04 increased risk of OCB negative MS compared with OCB positive MS (p-value = 1.46 × 10^{-5}, OR = 1.80, 95% CI = 1.44–2.25) (data not shown).

To refine the HLA-DRB1 association, we used HLA-DRB1 genotypes of four-digit resolution available for 1652 of the Norwegian MS samples and 890 healthy Norwegian controls (Table 4). Comparing OCB negative (n = 199) and OCB positive (n = 1453) MS patients showed that HLA-DRB1*15:01 and HLA-DRB1*04:04 were significantly differently distributed between OCB positive and OCB negative MS patients (p_{15:01} = 9.9 × 10^{-5}, OR = 0.64, 95% CI 0.49–0.83, p_{04:04} = 0.0004, OR = 2.2, 95% CI = 1.5–3.20). As expected, the HLA-DRB1*15:01 subtype accounted for the majority of the HLA-DRB1*15 allele group (99.8% in the OCB positive patients and 100% in the OCB negative patients). On the other hand, the HLA-DRB1*04:04 subtype accounted for a larger proportion of DRB1*04 among the OCB negative patients (43.7%) than the OCB positive (34.1%).

**Shared Effects at the HLA-DRB1*15:01, *01:01, *07:01 and Opposite Effects at the HLA-DRB1*04:04 Allele**

Compared to healthy controls the HLA-DRB1*15:01 was a risk allele for both CSF subtypes, but conferred a stronger risk on OCB positive than OCB negative MS (OCB positive; p-value = 2.57 × 10^{-5}, OR = 2.94, 95% CI = 1.53–3.20, OR = 1.88). On the other hand, HLA-DRB1*04:04 was seen to increase risk of OCB negative MS (p-value = 0.02, OR = 1.38), but confer protection to OCB positive MS (p-value = 0.04, OR = 0.71). HLA-DRB1*01:01 and HLA-DRB1*07:01 and HLA-DRB1*13:01 alleles were seen to reduce the risk of both OCB negative and OCB positive MS (OCB negative; p_{01:01} = 7 × 10^{-5}, OR = 0.45, p_{07:01} = 6 × 10^{-5}, OR = 0.57, p_{13:01} = 0.01, OR = 0.69, OCB negative; p_{01:01} = 2 × 10^{-5}, OR = 0.41, p_{07:01} = 0.05, OR = 0.63, p_{13:01} = 0.04, OR = 0.59). DRB1*04:01 was associated with protection for OCB positive MS only (p-value = 0.0005, OR = 0.65) (Figure 1).

Since the HLA-DRB1*15:01 allele appeared as a strong risk allele skewing the overall allele distribution at HLA-DRB1, we next analyzed the association of the other DRB1 alleles after stratification for DRB1*15:01 to test if these associations represented real risk effects. The association between OCB negative MS and HLA-DRB1*04:04 remained significant (p-value = 0.01), but became non-significant in the OCB positive group (p-value = 0.74) (Table 4). Associations to HLA-DRB1*01:01 and *07:01 were reduced, but still nominally significant, whereas the associations detected at the *13:01 and *04:01 alleles were non-significant.

Association of HLA-DRB1*03:01 (p-value = 0.0006, OR = 1.5) to OCB positive MS was revealed. When looking at the genotype distribution, the DRB1*03:01 association could be explained by excess homozygosity of HLA-DRB1*03:01 in OCB positive patients (frequency = 3.3%) compared to controls (frequency = 1.4%), leading to a higher frequency of the HLA-DRB1*03:01 allele in the patients. The OCB negative group also showed higher frequency of HLA-DRB1*03:01 homozygotes (frequency = 4%) compared to controls.

**Discussion**

This study reports the results of a genome-wide screening and subsequent replication of a genotype-OCB phenotype analysis in a total of 4931 genetically homogeneous Scandinavian MS patients. In all stages of the study, we found strong evidence that genetic differences relating to OCB status of Scandinavian MS patients could be exerted by HLA class II loci. All HLA associated SNPs in the screening phase were located in or near HLA class II genes. Further, high correlation coefficients were estimated between the top hit HLA SNPs in the screening and the HLA-DRB1*15 and *04 alleles. Accordingly, we found no evidence of association in Norwegian samples included in the screening to any of the identified HLA-SNPs when association to HLA-DRB1*15 or *04 alleles were accounted for in conditional logistic regression analyses. Of note, the SNP used to tag HLA-DRB1*15:01 in the MS GWAS (rs3129934) [3] yielded a p-value of 5.13 × 10^{-5} in the screening phase (data not shown), supporting association of HLA-DRB1*15:01 to OCB status. Analyses of HLA-DRB1*15:01 alleles indeed showed that OCB positive and OCB negative MS differ by their association to HLA-DRB1*15. Moreover, HLA-DRB1*15:01 was a common risk factor for both OCB negative and OCB positive MS, but exerted a stronger effect on OCB positive MS. On the other hand, the HLA-DRB1*04:04 allele showed opposite effects in the two patient groups, i.e. increasing risk of OCB negative MS.

Abbreviations: HLA = Human Leukocyte antigen, p_{cond} = p value of the annotated HLA SNP in logistic regression analyses conditioning on the HLA-DRB1*15 (p_{cond}^{*15}) or *04 (p_{cond}^{*04}) alleles, correlation*15 = correlation coefficient r between annotated HLA SNP and the HLA-DRB1*15 allele, correlation*04 = correlation coefficient r between annotated HLA SNP and the HLA-DRB1*04 allele.

doi:10.1371/journal.pone.0058352.t003

and somewhat protecting against OCB positive MS. These results confirm the findings from a previous, smaller Swedish study [12].

In addition, we showed that HLA-DRB1*01:01 and *07:01 reduce risk of OCB negative and OCB positive MS. Protective effects of HLA-DRB1*07 and *01:01 to MS have previously been reported [25,28,29]. HLA-DRB1*03:01 showed association to OCB positive MS after stratification for HLA-DRB1*15:01 and higher frequencies of homozygotes for the HLA-DRB1* 03:01 allele were seen in both OCB negative and OCB positive MS compared to controls. This complies with an earlier reported recessive risk for MS conferred by the HLA-DRB1*03 allele [30]. Our data also strongly suggested that rs17411949 in intron 1 of the CLSTN2 gene at chromosome 3 increased the risk of OCB negative MS. Variants of this gene have been reported to be associated with memory and late onset Alzheimer’s disease in GWASs, but with inconsistent replication [31–33]. CLSTN2 is predominantly expressed in the brain and is localized in the postsynaptic membrane of excitatory synapses where it binds synaptic Ca$^{2+}$ [34]. However, CLSTN2 is also expressed in bone marrow, tonsils and Daudi cells (B cell lymphoma) ([http://genome.ucsc.edu/](http://genome.ucsc.edu/)), and might have an immunological function. Further analyses are required to conclude on the indicated association of this SNP in OCB negative MS.

The relatively low number of OCB negative patients in the screening phase represents a natural limitation in this study, since only approximately 10% of MS patients are negative for OCB. Nevertheless, this study sample is probably the largest available to date investigating OCB phenotype. Power calculations showed that with our sample size in the screening phase, the effect size would need to be OR >2 in order to have 80% power to detect differences between OCB positive and OCB negative MS at a significance level of p < 10$^{-5}$ ([http://ihg2.helmholtz-muenchen.de/cgi-bin/hw/power2.pl](http://ihg2.helmholtz-muenchen.de/cgi-bin/hw/power2.pl)). Hence the p < 10$^{-5}$ cut off in the screening phase could mean that we missed true association of ORs <2. A recent study of a German and Belgian MS patient population reported genome-wide significant association between quantitative IgG index and a genetic region different from the findings described in our study, i.e. the IgHGC locus [35]. However, the results of these two studies are not conflicting but complementary, due to the analysis of differently defined CSF parameters. Hence, the observed CSF phenotype-genotype associations in our and the German-Belgian study probably have different biological implications.

A possible confounding factor in our study is that different methods were used for OCB detection since sample collection has been ongoing through many years. The most sensitive method for OCB detection is IEF [8]. Samples which were collected prior to the introduction of this method, were investigated by less sensitive methods, i.e. AGE or IgG index. Since AGE, which was used to annotate OCB negative MS, is less sensitive than IEF, some of the earlier collected samples may have been falsely regarded as OCB negative. However, this would in worst case deflate the association seen to the OCB negative group, rather than create falsely positive association, and hence it should not invalidate our positive findings.

Clinical studies support differences in the outcome in OCB positive and OCB negative patient groups, albeit with contrasting findings. In our combined clinical analysis of this Scandinavian dataset, we find a significantly older AAO in the OCB negative patients (p-value = 0.01), a trend previously indicated in other studies [12,16]. A recent study validated this finding and showed a small, but very significant effect (OR 0.98, p<0.0001) of OCB status on AAO [10]. The older AAO in the OCB negative group also speaks against false inclusion of OCB negative patients caused by lumbar punctures performed in early stages of disease, when the rate of OCB detection is reported to be lower [36]. We also found a significantly lower MSSS among the OCB negative patients included in the replication analysis and the combined analysis (p-value = 0.02). This is in accordance with most studies of clinical differences related to OCB status, which suggest a better outcome for MS patients without OCB, as measured by lower degree of disability, lower frequencies of exacerbations and slower progression [10,11,13,15]. On the other hand, a recent Canadian study in 1120 MS patients did not find any relation between OCB status and disease progression [37]. The conflicting findings concerning OCB status and clinical outcome, require further studies. Finally, therapeutic studies have reported that OCB negative patients are less likely to develop neutralizing antibodies.
to interferon-beta treatment and show better clinical response to this treatment than their OCB positive counterparts [38,39].

OCB status and the frequency of the HLA-DRB1*15:01 allele have been shown to vary with latitude [10,40]. In countries like Sardinia, Japan and Turkey where about five times higher ratios of OCB negative/OCB positive MS are reported compared to Northern Europe, MS risk has been shown to be conferred by both HLA-DRB1*04 and HLA-DRB1*15:01 [10,12,19,41,42].

Hence, we speculate that the HLA-DRB1*15:01 allele possibly interacts with environmental agents in areas where this allele is common, making a population more prone to OCB positive MS. The HLA-DRB1*04 allele may, on the other hand, confer risk of OCB negative MS by different immuno-genetic mechanisms.

In conclusion, this study points to both distinct and shared genetic risk factors in Scandinavian MS patients differing by the presence or absence of OCB in CSF and reveals clinical differences between the groups. Risk conferred by HLA-DRB1*15:01 was present in both OCB positive and negative groups, but was much stronger in the OCB positive group. HLA-DRB1*04:04 conferred risk for OCB negative MS and protection of OCB positive MS. HLA-DRB1*01:01 and *07:01 conferred protection irrespective of OCB status. Moreover, a SNP in the CLSTN2 gene was associated with increased risk of OCB negative MS, but requires validation in further studies. The OCB negative patients had a significantly lower MSSS, were more likely to be male and had a later age of MS onset. The identified genetic and clinical differences relating to OCB status in MS may reflect variation in disease mechanisms and possibly be of importance for patient management.

Supporting Information

Table S1 SNPs showing association in the screening phase to OCB status of MS (p<10^-5).

| Alleles | Frequency (%) | OR (95% CI) | p | OR (95% CI) | p | OR (95% CI) | p |
|---------|---------------|-------------|---|-------------|---|-------------|---|
| HLA-DRB1* allele | OCB negative | OCB positive | Controls | OCB negative | OCB positive | Controls |
| *15:01 | 25.1 | 15.1 | 11.1 | 2.93 (1.59-6.17) | 0.012 | 0.62 (0.40-0.99) | 0.05 |
| *04:04 | 15.3 | 11.1 | 8.8 | 2.26 (1.25-2.96) | 0.001 | 0.74 (0.58-0.95) | 0.02 |
| *07:01 | 6.3 | 5.7 | 5.9 | 1.18 (0.70-2.01) | 0.57 | 0.64 (0.44-0.91) | 0.03 |

Abbreviations: n: total Norwegian samples available with HLA-DRB1* alleles of 4 digit solution, i.e. MS patients from the screening and replication are pooled. OCB: oligoclonal bands, OR: odds ratio, CI: confidence interval.

Figure 1. HLA-DRB1 alleles with significant effects on OCB positive and negative MS. Figure 1 shows the ORs and 95% CI for HLA-DRB1 alleles with significant effects on OCB positive and negative MS. Only alleles which remain significant after stratification for HLA-DRB1*15:01 allele in both groups are included, except HLA-DRB1*04:04 (not withstanding stratification in the OCB positive group) and HLA-DRB1*07:01 (associated to OCB negative MS only after stratification). These exceptions are marked (*).
