I. INTRODUCTION

In classical general relativity, if one wishes to study spacetime properties that hold for a variety of matter sources it is suitable to impose the so-called energy conditions that limit the arbitrariness of the energy-momentum tensor $T_{μν}$ on physical grounds. These conditions can be stated in a coordinate-invariant way in terms of $T_{μν}$ and vector fields of fixed character (time-like, null and spacelike). However, within the framework of the standard Friedmann-Lemaître-Robertson-Walker (FLRW) model, we only need to consider the energy-momentum tensor of a perfect fluid with density $ρ$ and pressure $p$, i.e.,

$$T_{μν} = (ρ + p) u_μ u_ν - p g_{μν}, \quad (1)$$

so that the energy conditions take one of the following forms $[1, 2, 3]:$

NEC : $ρ + p ≥ 0$ ,

WEC : $ρ ≥ 0$ and $ρ + p ≥ 0$ ,

SEC : $ρ + 3p ≥ 0$ and $ρ + p ≥ 0$ ,

DEC : $ρ ≥ 0$ and $-ρ ≤ p ≤ ρ$ ,

where NEC, WEC, SEC and DEC correspond, respectively, to the null, weak, strong and dominant energy conditions. Clearly, the ordinary matter in the form of baryons or relativistic particles like photons and neutrinos satisfies these energy conditions.

From the theoretical point of view, the energy conditions have been used in different contexts to derive powerful results in a variety of situations. For example, the Hawking-Penrose singularity theorems invoke the SEC $[1]$, the positive mass theorem assumes the DEC $[4]$, while the proof of second law of black hole thermodynamics requires NEC $[3, 5]$.

On macroscopic scales relevant for cosmology, another important viewpoint is the confrontation of the energy condition predictions with the observational data. In this regard, since the pioneering works by Visser $[6]$, it has been shown that the energy conditions provide model-independent bounds on the cosmological observables, and a number of studies involving such bounds have been recently discussed in the literature $[7, 8, 9, 10, 11, 12, 14, 15]$ (see also the related Refs. $[16]$). Santos et al. $[7, 8]$ have derived bounds on the distance modulus, $μ(z)$, for any spatial curvature $k$, and made a confrontation of the bound predictions with recent type Ia supernovae (SNe Ia) data. In Refs. $[9, 10]$ the confrontation of the NEC and SEC bounds with a combined sample of 192 supernovae was carried out providing similar and complementary results. They have also shown that the violation of integrated bounds [such as those on $μ(z)$] at a given redshift $z$ ensures the breakdown of the corresponding energy condition, without specifying at what redshift the energy-condition violation took place. In Ref. $[11]$ model-independent energy-conditions bounds on the lookback...
time, \( t_L(z) \), was derived and a confrontation with age estimates of galaxies was made. Sen and Scherrer \(^{12}\) derived upper limits on the matter density parameter \( \Omega_m \) from the WEC in a flat \((k = 0)\) universe. In the recent Ref. \cite{13}, Cattoën and Visser have reviewed and complemented some aspects of Refs. \cite{6, 7, 8, 11}. Energy conditions constraints on modified gravity models, such as the so-called \( f(R) \)-gravity, have also been investigated in Ref. \cite{14} and more recently in Ref. \cite{15}.

In this paper, to proceed further with the investigation of the interrelation between energy conditions on scales relevant for cosmology and observational data, we extend and complement the results of Refs. \cite{6, 7, 8, 11} in three different ways. First, we show in a simple way that the violation of \textit{integrated bounds} such as those on the Hubble parameter \( H(z) \), on the distance modulus \( \mu(z) \) \cite{6, 11} and on the lookback time \( t_L(z) \) \cite{11} at a redshift \( z \) is neither necessary nor sufficient \textit{local condition} for the breakdown of the associated energy condition \cite{6, 11}. Second, we derive \textit{local necessary and sufficient} bounds for the fulfillment of each energy condition in terms of the deceleration parameter \( q(z) \) and the normalized Hubble function \( E(z) = H(z)/H_0 \) for any spatial curvature. Third, we make the confrontation between our \textit{local non-integrated bounds} with statistical estimates [in the plane \( E(z) - q(z) \)] by using the SNe Ia of both the new gold sample \cite{17}, of 182 SNe Ia and the \textit{combined} sample of 192 SNe Ia \cite{18}. In this way, our necessary and sufficient non-integrated energy-condition bounds allow a statistical confrontation of energy conditions and SNe Ia data within chosen confidence levels at any given redshift.

\section{II. Integrated Bounds from the Energy Conditions}

In this section we give an account of our basic assumptions, briefly recast the major results of Refs. \cite{6, 7, 8, 11}, and discuss the nature of the energy-condition \textit{integrated} bounds and their limitation in the local confrontation with observational data.

Let us begin by recalling that the standard approach to cosmological modelling commences with a space-time manifold endowed with the Friedmann-Lemaitre-Robertson-Walker (FLRW) metric

\[
ds^2 = dt^2 - a^2(t) \left[ \frac{dr^2}{1 - kr^2} + r^2(d\theta^2 + \sin^2 \theta d\phi^2) \right], \tag{3}
\]

where the spatial curvature \( k = 0, 1 \) or \(-1\) and \( a(t) \) is the cosmological scale factor. The metric \cite{8} encodes the assumption that our 3-dimensional space is homogeneous and isotropic at sufficiently large scales along with the existence of a cosmic time \( t \). However, to study the dynamics of the Universe an additional assumption in this approach to cosmological modelling is necessary, namely, that the large scale structure of the Universe is essentially governed by the gravitational interactions, and hence can be described by a metrical theory of gravitation such as general relativity (GR).

These very general premises, which we assume in this work, constrain the cosmological fluid to be a perfect-type fluid of the form \cite{11}, with the total density \( \rho \) and pressure \( p \) given by

\[
\rho = \frac{3}{8\pi G} \left[ \frac{a^2}{a^2} + \frac{k}{a^2} \right], \quad \tag{4}
\]

\[
p = -\left[ \frac{1}{8\pi G} \left( 2 \frac{\ddot{a}}{a} + \frac{a^2}{a^2} + \frac{k}{a^2} \right) \right], \quad \tag{5}
\]

where dots denote derivative with respect to the time \( t \).

The \textit{integrated} bounds on the Hubble functions \( H(z) \) comes from the following set of dynamical constraints:\footnote{In line with the usage in Refs. \cite{6, 7, 11}, here and in what follows we use the boldface-type to denote the energy-condition restriction that is not contained in any of the previous set of energy-conditions inequations [see Eqs. (3)]. In this way, NEC, WEC, SEC and DEC refer, respectively, to the following NEC, WEC, SEC and DEC inequations: \( \rho + p \geq 0 \), \( \rho \geq 0 \), \( \rho + 3p \geq 0 \), and \( \rho - p \geq 0 \).}

\begin{align*}
\text{NEC} & \Rightarrow \frac{\ddot{a}}{a} + \frac{k}{a^2} \geq 0, \quad \tag{6} \\
\text{WEC} & \Rightarrow \frac{\ddot{a}}{a} + \frac{k}{a^2} \geq 0, \quad \tag{7} \\
\text{SEC} & \Rightarrow \frac{\ddot{a}}{a} \leq 0, \quad \tag{8} \\
\text{DEC} & \Rightarrow \frac{\ddot{a}}{a} + 2 \left[ \frac{a^2}{a^2} + \frac{k}{a^2} \right] \geq 0, \quad \tag{9}
\end{align*}

which can be easily derived from the energy conditions [Eqs. (1)] along with the above Eqs. (4) and (5). In fact, Eqs. (6–9) can be written in terms of the Hubble function, \( H(z) = \dot{a}(t)/a(t) \), and its derivatives with respect to the redshift, \( z = (a_0/a) - 1 \), as

\begin{align*}
\text{NEC} & \Rightarrow \frac{\partial H^2}{\partial z} \geq -\frac{2k(1 + z)}{a_0^2}, \quad \tag{10} \\
\text{WEC} & \Rightarrow \frac{k(1 + z)^2}{a_0^2 H^2} \leq 1, \quad \tag{11} \\
\text{SEC} & \Rightarrow \frac{\partial \log H^2}{\partial z} \geq \frac{2}{(1 + z)}, \quad \tag{12} \\
\text{DEC} & \Rightarrow \frac{\partial}{\partial z} \left( \frac{H^2}{(1 + z)^5} \right) \leq -\frac{4k}{a_0^2(1 + z)^5}, \quad \tag{13}
\end{align*}

where here and in what follows the subscript \( 0 \) stands for present-day quantities. Now, integrating the inequations \cite{10, 11} and \cite{13} in the interval \((0, z)\), where we assume that they hold, one obtains the following \textit{integrated} bounds on Hubble function from the energy con-
ditions:

\[ \text{NEC} \Rightarrow H(z) \geq H_0 \sqrt{1 - \Omega_{\Lambda 0} + \Omega_{\kappa 0}(1 + z)^2}, \]  
\[ \text{SEC} \Rightarrow H(z) \geq H_0(1 + z), \]  
\[ \text{DEC} \Rightarrow H(z) \leq H_0(1 + z)\sqrt{(1 - \Omega_{\kappa 0})(1 + z)^4 + \Omega_{\kappa 0}). \]

We note that the inequation (13) does not contain derivative of \( H(z) \), but clearly for \( z = 0 \) the \( \text{WEC} \) restricts the present-day curvature parameter to \( \Omega_{\kappa 0} \equiv -k/(\Omega_0 H_0)^2 \leq 1 \).

The \textit{integrated} bounds provided by the energy conditions on the distance modulus \( \mu(z) \) can now be easily obtained from the above bounds on the Hubble function as follows. First, we recall that the distance modulus for an object at redshift \( z \) is defined by

\[ \mu(z) \equiv m(z) - M = 5 \log_{10}\left( \frac{d_L(z)}{1\text{Mpc}} \right) + 25, \tag{17} \]

where \( m \) and \( M \) are, respectively, the apparent and absolute magnitudes, and \( d_L \) is given by

\[ d_L(z) = \frac{c}{H_0} \frac{(1 + z)}{\sqrt{|\Omega_{\kappa 0}|}} S_k \left( \sqrt{|\Omega_{\kappa 0}|} \int_0^z \frac{dz'}{E(z')} \right), \tag{18} \]

where \( S_k(x) = \sin(x), x, \sinh(x) \) for \( k = 1, 0, -1 \) respectively, and \( E(z) = H(z)/H_0 \). Second, we substitute Eqs. (14)–(16) into Eqs. (18) and (17) to obtain the bounds on the distance modulus \( \mu(z) \) for any spatial curvature \( k \). For the flat FLRW model (\( \Omega_{\kappa 0} = 0 \)) which we focus our attention on in this paper, the \textit{integrated} bounds reduce to

\[ \text{NEC} \Rightarrow \mu(z) \leq 5 \log_{10}[cH_0^{-1}z(1 + z)] + 25, \tag{19} \]
\[ \text{SEC} \Rightarrow \mu(z) \leq 5 \log_{10}[cH_0^{-1}(1 + z) \ln(1 + z)] + 25, \tag{20} \]
\[ \text{DEC} \Rightarrow \mu(z) \geq 5 \log_{10}[cH_0^{-1}(1 + z)^2] / [2(1 + z)] + 25. \tag{21} \]

Concerning the above bounds on \( H(z) \) and \( \mu(z) \), we emphasize that the \textit{nonlocal} or \textit{integrated} nature of these bounds arises from the fact that they were obtained by assuming the fulfillment of the energy condition in the whole interval of integration \((0, z)\). However, in the same way that a positive sum of \( N \) terms does not necessarily imply that all the terms of the sum are also positive, the fulfillment of the \textit{integrated} bounds on \( H(z) \) and \( \mu(z) \) does not necessarily imply that the energy conditions are obeyed in all subintervals of \((0, z)\) but only in at least an undetermined subinterval. Reciprocally, the violation of these \textit{integrated} bounds merely implies that the corresponding energy condition was violated in at least a subinterval of \((0, z)\). This amounts to saying that the fulfillment (or the violation) of any of these bounds at a given redshift \( z \) is not a sufficient (nor a necessary) \textit{local} condition for the fulfillment (or respectively the violation) of the associated energy condition at \( z \). In practice, this means that the local confrontation between the prediction of the \textit{integrated} bounds such as those on \( H(z) \) and on \( \mu(z) \) [Eqs. (14)–(16)] and [Eqs. (19)–(21)] and observational data is not suitable to draw conclusions on the local fulfillment or violation of the associated energy conditions at \( z \).

III. NON-INTEGRATED BOUNDS FROM THE ENERGY CONDITIONS

The practical limitation in the local confrontation between the above \textit{integrated} bounds and observational data calls for \textit{non-integrated} bounds from energy conditions, which can be easily obtained by rewriting Eqs. \( (6) - (9) \) in terms of the deceleration parameter, \( q(z) = -d/\Omega_0 H^2 \), and the normalized Hubble function, \( E(z) = H(z)/H_0 \), in the following form:

\[ \text{NEC} \Leftrightarrow q(z) - \Omega_{\Lambda 0} \left( \frac{1 + z}{E^2(z)} \right) \geq -1, \tag{22} \]
\[ \text{WEC} \Leftrightarrow \frac{E^2(z)}{(1 + z)^2} \geq \Omega_{\Lambda 0}, \tag{23} \]
\[ \text{SEC} \Leftrightarrow q(z) \geq 0, \tag{24} \]
\[ \text{DEC} \Leftrightarrow q(z) + 2 \Omega_{\kappa 0} \left( \frac{1 + z}{E^2(z)} \right) \leq 2. \tag{25} \]

for any spatial curvature \( \Omega_{\kappa 0} \).

Some words of clarification are in order here concerning the above bounds. First, we note that for a fixed value of \( \Omega_{\kappa 0} \), Eq. (23) provides the \textit{WEC} lower-bound on normalized Hubble function \( E(z) \) for any \( z \), whereas Eqs. (22) and (24) give, respectively, the \textit{NEC} and \textit{DEC} bounds on parameters of \( E(z) - q(z) \) plane for any fixed redshift \( z \), (say). Also, the \textit{SEC} lower bound [Eq. (24)] clearly holds regardless of the value of the spatial curvature. Second, since the bounds have been derived without making any integration (\textit{non-integrated} bounds), they are clearly sufficient and necessary to ensure the \textit{local} fulfillment of the associated energy condition. In practice, this allows local confrontation between the predictions of these \textit{non-integrated} bounds and, e.g., SNe Ia data, an issue which we shall discuss in the following sections focusing in the flat \((k = 0)\) FLRW case, in which the \textit{NEC} and \textit{DEC} \textit{non-integrated} bounds reduce, respectively, to \( q(z) \geq -1 \)

\[ 2 \text{We note that at a nonlocal level, the fulfillment (or the violation) of each of these \textit{integrated} bounds at a given \( z \) is sufficient to ensure only the fulfillment (or respectively the violation) of the associated energy conditions somewhere in at least a subinterval of the integration interval \((0, z)\), as discussed in Refs. \cite{9, 10} and concretely illustrate in Section IV B.} \]
and $q(z) \leq 2$, and where obviously the fulfillment of the SEC $[q(z) \geq 0]$ implies that the NEC is satisfied identically.

IV. ANALYSIS AND DISCUSSION

A. Estimates of $q(z_*)$ and $E(z_*)$

In order to make the confrontation between the non-integrated bounds [Eqs. (22)–(24)] with observational data we need estimates of $q(z_*)$ and $E(z_*)$. Model-independent estimates of these parameters can be obtained by approximating the deceleration parameter as a function of the redshift in terms of a linear piecewise continuous function, known as linear spline,

$$q(z) = q_i + q_i^t \Delta z_i, \quad z \in (z_i, z_i+1),$$

where the subscript $t$ means that the quantity is taken at $z_i$, $\Delta z_i \equiv (z - z_i)$, and the prime means the derivative with respect to $z$. We use the definition of $q(z)$ in terms of $H(z)$ to obtain

$$E(z) = \exp \int_0^z \frac{1 + q(z)}{1 + z} \, dz,$$

and, consequently, the luminosity distance and the distance modulus using Eqs. (18) and (17). Then we fitted the parameters of the $q(z)$ curve using the type Ia supernovae (SNe Ia) redshift–distance modulus data from gold sample and a combined sample.

B. Results

In Figs. (a) and (b) we confront the NEC along with DEC, and the SEC integrated bounds on $\mu(z)$ [Eqs. (19), (21) and (22)] with SNe Ia of the combined sample as compiled in Ref. 18 for, respectively, the redshift intervals $(0.02, 0.055)$ and $(0.3, 0.8)$ by taking consistently $H_0 = 65.8$ km s$^{-1}$ Mpc$^{-1}$. Clearly there are several SNe data points indicating the violation with more than 1$\sigma$ of the integrated NEC and SEC upper-bounds on $\mu(z)$, and two data points suggesting the violation of the integrated DEC lower-bound on the distance modulus with $\geq 1\sigma$.

To concretely contrast the integrated and non-integrated bounds by using supernovae observations, we consider, as a first example, the supernova 1992bh at $z = 0.0451$ of the combined sample, whose observed distance modulus is $\mu_{1992bh} = 36.91 \pm 0.19$ while the upper-bound NEC predictions is $\mu(z = 0.0451) = 36.66$, i.e., it violates the integrated upper-bound from NEC with $\simeq 1.31\sigma$ [see Fig. (a)]. However, this local violation of the NEC integrated bounds is not sufficient to guarantee the breakdown of the NEC at $z = 0.0451$. This point is made apparent in Fig. (b) which shows the $1\sigma$, $2\sigma$ and $3\sigma$ confidence regions in the plane $E(z) - q(z)$ [estimated from combined sample at $z_* = 0.0451$] along with the non-integrated (local) NEC bound $[q(z) \geq -1]$. Clearly, the fact that the whole $1\sigma$ confidence region is above the NEC non-integrated bound is sufficient to ensure the fulfillment of the NEC with $1\sigma$ at $z_* = 0.0451$, despite the $\simeq 1.31\sigma$ violation of the NEC integrated bound at this redshift.

Figures (b) and (b) show the contrast between the SEC integrated and non-integrated bounds. In Fig. (b) the supernova 03Dico (which belongs to the combined and gold samples) at $z_* = 0.679$, is such that its observed value of the distance modulus [gold: $\mu = 43.58 \pm 0.19$, combined: $\mu = 43.59 \pm 0.27$] violated the SEC integrated upper-bound predictions [gold: $\mu = 43.06$, combined: $\mu = 42.99$] with $2.22\sigma$ (gold) and $2.72\sigma$ (combined). Fig. (b) shows the $1\sigma$, $2\sigma$ and $3\sigma$ confidence regions in the plane $E(z) - q(z)$ [estimated from gold and combined sample at $z_* = 0.679$] along with the non-integrated SEC lower-bound $[q(z) \geq 0]$. The comparison of these figures makes clear that although the observed $\mu(z)$ values are more than $2\sigma$ higher than the SEC integrated upper-bounds (suggesting at first sight a violation of the SEC) the non-integrated bound analysis shows that at $z_* = 0.679$ the SEC can either be fulfilled or violated within $1\sigma$, $2\sigma$ and $3\sigma$ confidence levels for both SNe Ia samples.

In order to obtain a detailed global picture of the breakdown and fulfillment of the energy conditions in the recent past, we shall extend the above local analysis by examining the behavior of the non-integrated energy-condition bounds with $1\sigma - 3\sigma$ confidence levels for the recent past $(0 < z \leq 1)$ using the combined and gold SNe Ia samples. To this end, we first divide the redshift interval $(0.1]$ into 100 equally spaced points at which we carry out the statistical estimates and confrontation of the non-integrated bounds with SNe Ia data. Second, we note that, for the flat case, the NEC, SEC and DEC non-integrated bounds do not depend on the estimates of $E(z_*)$ [see Eqs. (23), (24), (25)] and Fig. 2, and therefore the upper and lower $1\sigma - 3\sigma$ limits of $q(z_*)$ are sufficient to establish the fulfillment or violation of

\[\text{REF}]

\[\text{http://braeburn.pha.jhu.edu/~ariess/R06/}\] the distance modulus is computed using an arbitrary choice of the absolute magnitude $M$ as discussed in Ref. 17 and 18. In Fig. (a) and Fig. (b) we have dealt with this arbitrariness by noting that the confrontation between the integrated bounds [Eqs. (19)–(21)] with SNe Ia data depends on $H_0$ and $M$ through the additive term $m_0 = M + 5 \log_10\left(\frac{cH_0}{H_0}\right)$. Thus, to obtain a value of $m_0$ consistent with the SNe data, we have fitted the low redshift ($z \leq 0.3$) SNe Ia distance modulus treating $H_0$ as an unknown and taking the values of magnitude $M$ as given by the combined sample. Clearly, this procedure for comparison between bounds with SNe Ia data is independent of a particular value of $H_0$ in the sense that one can also begin by taking a specific value of $H_0$, adjust the value of $m_0$, and treating $M$ as unknown instead.

\[\text{REF}]

\[\text{http://braeburn.pha.jhu.edu/~ariess/R06/}\] the distance modulus is computed using an arbitrary choice of the absolute magnitude $M$ as discussed in Ref. 17 and 18. In Fig. (a) and Fig. (b) we have dealt with this arbitrariness by noting that the confrontation between the integrated bounds [Eqs. (19)–(21)] with SNe Ia data depends on $H_0$ and $M$ through the additive term $m_0 = M + 5 \log_10\left(\frac{cH_0}{H_0}\right)$. Thus, to obtain a value of $m_0$ consistent with the SNe data, we have fitted the low redshift ($z \leq 0.3$) SNe Ia distance modulus treating $H_0$ as an unknown and taking the values of magnitude $M$ as given by the combined sample. Clearly, this procedure for comparison between bounds with SNe Ia data is independent of a particular value of $H_0$ in the sense that one can also begin by taking a specific value of $H_0$, adjust the value of $m_0$, and treating $M$ as unknown instead.
FIG. 1: Panel (a): The NEC upper-bound and the DEC lower-bound on the distance modulus, $\mu(z)$, in the redshift interval $(0.02, 0.055)$. Panel (b): The SEC upper-bound on $\mu(z)$ in the redshift interval $(0.3, 0.8)$. The data points in both panels correspond to type Ia supernovae from a combined sample, and consistently we have taken $H_0 = 65.8 \, \text{km s}^{-1} \, \text{Mpc}^{-1}$.

FIG. 2: The $1\sigma$, $2\sigma$ and $3\sigma$ contours obtained with the $E(z_\star)$ and $q(z_\star)$ estimates from combined (solid lines) and gold (dashed lines) samples at $z_\star = 0.0451$ [panel (a)] and at $z_\star = 0.679$ [panel (b)]. The non-integrated SEC and NEC bounds are also indicated. The best fit values for $(E(z), q(z))$ at $z = 0.0451$ are $(1.015,-0.638)$ for gold, and $(1.020,-0.559)$ for combined. At $z_\star = 0.679$ the best fit values are $(1.621,0.469)$ for gold, and $(1.464,0.215)$ for combined sample.

these energy conditions within these confidence levels.

The two panels in Fig. 3 show the best-fit values and $1\sigma$, $2\sigma$ and $3\sigma$ limits for $q(z_\star)$ for the combined [panel (a)] and gold [panel (b)] samples along with the non-integrated NEC, SEC and DEC bounds in the plane $q(z) - z$. These panels indicate the violation of the SEC with more than $3\sigma$ confidence level in the redshift intervals $(\approx 0.09, \approx 0.17)$ and $(\approx 0.11, \approx 0.16)$ for, respectively, the gold and combined samples. We note that highest evidence for the violation of SEC is at $z \approx 0.135$ for both samples $[3.86\sigma$ (combined) and $3.43\sigma$ (gold) below the bound]. Clearly, violation of the SEC is also permitted (within $1\sigma$ to $3\sigma$) for higher redshifts, but the best-fit $q(z_\star)$ curves cross the SEC-fulfillment divider at $z \approx 0.67$ and $z \approx 0.42$ for the combined and gold samples, respectively.

Concerning the NEC, the panels of Fig. 3 show its violation within $3\sigma$ for low redshifts $[z \in (0, \approx 0.1)]$ for combined and gold samples. For higher values of redshift we have the NEC-fulfillment with $2\sigma$ for both samples.\footnote{Since the violation of the integrated bounds at any $z$ ensures}$^4$

Regarding the DEC, Fig. 3 shows that it is fulfilled in

\footnote{Since the violation of the integrated bounds at any $z$ ensures}
nearly the whole redshift interval for both samples, but it might be violated within $3\sigma$ for high redshifts ($z \gtrsim 0.8$), where the errors in our estimates grow significantly, though.

Concerning the above analyses it is worth emphasizing that they are very insensitive to the values of the curvature parameter, i.e., all the above conclusions remain essentially unchanged for values of $\Omega_0$ lying in the interval provided by the WMAP and other experiments [19]. In other words, our estimates of $E(z_*)$, $q(z_*)$ and of the non-integrated bounds [Eqs. (22)–(25)] by using the best-fit value, the upper or the lower $1\sigma$ limits for $\Omega_0 = -0.014 \pm 0.017$ [19] are very close to estimates of those parameters in the flat case, with differences much smaller than the associated errors.

Finally, we also note that the non-integrated WEC bound [Eq. (23)] is fulfilled in the whole redshift interval $(0,1)$ for the upper $1\sigma$ limit value of the curvature provided by WMAP team, i.e., $E^2(z) \gtrsim 0.003 (1+z)^2$ holds for all our estimated values of $E(z_*)$, whereas for the $\Omega_0 \in (-0.031,0)$ the WEC is fulfilled identically, i.e., regardless of the values of $E(z_*)$ and $z_*$.

V. CONCLUDING REMARKS

By using the fact the classical energy conditions can be recast as a set of differential constraints involving the scale factor $a(t)$ and its derivatives [see (6)–(9)], model-independent integrated bounds on, e.g., the Hubble parameter $H(z)$, the distance modulus $\mu(z)$, and on the lookback time $t_L(z)$ have been recently derived and confronted with observational data (see, e.g.,Refs. [6, 7, 8, 9, 10, 11, 13]).

In this paper, we have shown that the violation (or the fulfillment) of these integrated bounds at a given redshift $z$ is neither sufficient nor necessary to ensure the violation (or respectively the fulfillment) of the energy conditions at $z$. In practice, this means that the local confrontation between the prediction of the integrated bounds and observational data (such as, e.g., those in Refs. [7, 8, 11]) is not sufficient to draw conclusions on the violation or fulfillment the energy conditions at $z$. This feature is also made apparent in Figs. 1 and 2 where we present concrete examples of violation of integrated bounds with either fulfillment of the non-integrated bounds with $1\sigma$ [panels 1(a) and 2(a)], or fulfillment and violation of the non-integrated bounds with $1\sigma$, $2\sigma$ and $3\sigma$ [panels 1(b) and 2(b)].

To overcome the crucial drawback in the confrontation between integrated bounds on cosmological observables and observational data, we have formulated new bounds from energy conditions in terms of the normalized Hubble and deceleration parameters $[E(z)$ and $q(z)]$ which are necessary and sufficient for the fulfillment of the energy conditions [Eqs. (22)–(25)]. We have also confronted our non-integrated bounds with model indepen-
dent estimates of $q(z)$ and $E(z)$ which were obtained by using the gold sample of 182 SNe Ia provided by Riess et al. in Ref. [17] and with a combined sample of 192 SNe Ia provided by Wood-Vasey et al. [18] [Figs. 2 and 3. On general grounds, our analyses indicate the WEC fulfillment in the recent past ($z \leq 1$) with 3σ, and a possible recent phase of super-acceleration (violation of the NEC with 3σ for $z \in (0, 0.1)$ for both the combined and gold samples. Our analyses also show that the DEC is fulfilled with 3σ for all recent past redshifts but $z \geq 0.8$. Concerning the SEC our analyses indicate the possibility its violation with $1 - 3σ$ confidence levels for $z \leq 1$, with small subintervals in which there is no SEC-fulfillment with 3σ for both the combined and gold samples. An interesting fact from the confrontation between the SEC non-integrated bound and SNe Ia combined sample is that although the violation of the SEC is permitted in the recent past with 3σ confidence level, the estimated $q(z)$-best-fit curve crosses the SEC-fulfillment divider at $z \simeq 0.67$ [see panel (a)], which is very close to redshift of the beginning of the epoch of cosmic acceleration predicted by the current standard concordance flat $\Lambda$CDM scenario with $\Omega_m \simeq 0.3$.

Finally, we emphasized that although we have focused our attention on the flat FLRW case, the above results concerning the new non-integrated bounds analyses remain unchanged for values of $\Omega_k$ lying in the interval provided by WMAP team [19].
