Abstract
Autoimmune thyroiditis is very rare etiology of primary hypothyroidism in infancy. Hypothyroidism has a wide range of clinical presentation, from subclinical hypothyroidism to overt type. It is unclear what pathological mechanisms connect thyroid function and erythropoiesis or how thyroid disease can contribute to anemia. We report a 12-month-old infant who presented with anemia associated with early onset of overt autoimmune thyroiditis. The peculiarity of our case enables us to draw attention of physician to consider acquired hypothyroidism in the differential diagnosis of unexplained anemia even if the neonatal screening is normal and congenital hypothyroidism is a remote possibility.

Case Presentation
The twelve-month-old infant presented to the pediatric hematology clinic with unexplained normochromic normocytic anemia. At the age of 2 months, the child was admitted with fever, his full blood count showed low hemoglobin (HB) 8.7 mg/dL (normal range [N] 11.1–14.1 g/dL), low mean corpuscular volume (MCV) 76.7 fl (N; 87.0–103.0 fl), and low mean corpuscular HB 24.5 pg (N; 27.0–33.0 pg). This result was attributed to physiologic anemia of infancy. At the age of 7 months, he was readmitted with RSV pneumonia, HB was 8.7 mg/dL, MCV: 71.0 fl (N), and mean
corpuscular hemoglobin: 22.7 pg (low). Repeated full blood count showed a further decline of the HB level to 7.9 mg/dL. Red blood cell count was within normal limits: 3.83 and 3.56 x 10⁶/μL, respectively (N; 3.10–4.30 10⁶/μL). Platelet counts, as well as leukocyte count, were normal. Reticulocyte count was low: 0.3% (normal range 0.5–2.5%). Iron studies and quantitative G6PD levels were normal. Peripheral blood film was consistent with normocytic anemia with reduced bone marrow response to the anemia. The possibility of transient erythroblastopenia of childhood was raised. The child had torticollis; thus, he was referred to physiotherapy. He was discharged with HB: 9.1 mg/dL. At the hematology clinic, 2 weeks later, noted by the parents, the child was sleepy, dull-looking with no social interaction, poor concentration, and no eye contact; he was responding to his name. His developmental milestones were at an average of 9–10 months. By the age of 12 months, he stood without support but not yet walking, no pincer grasp, and not clapping hands but occasionally waves goodbye. He had constipation despite adequate water and fiber intake in his diet. On examination, he had normal growth parameters: weight at 10th centile and height reduced from the 36th centile to 3rd centile over 4 months (Fig. 1). He was pale, with bilateral periorbital puffiness, protruded tongue, sleepy, less interactive, no goiter, and mild right-sided torticollis. The remainder of the examination was unremarkable. HB level decreased to 8.2 g/dL. Leukocyte and platelet count remained normal. Reticulocyte count slightly increased from 0.3% to 0.7%. Iron studies were normal. HB electrophoresis was reported as normal. He was born at term by lower segment caesarian section, with a birth weight of 2.8 kg, and had an uneventful antenatal and postnatal period. The neonatal screening, which included TSH, was normal. Parents are 1st cousins; he has 2 elder siblings with no known medical concerns, and his mother has acquired hypothyroidism on thyroxine treatment. Paternal aunt and maternal grandmother have primary hypothyroidism; they are on treatment with thyroxine, no family history of known blood disorders. Hypothyroidism was clinically suspected, so thyroid function was sent. The report favored severe hypothyroidism with a very high TSH level: 516.4 μIU/mL (normal range: 0.9–6.5 μIU/mL) and low Free T4: 0.4 pmol/L (normal range 12.0–23.0 pmol/L). It is worth noting that the child’s neonatal screening for TSH was normal, and TSH at age of 1 week was normal: 7.860 μIU/mL (N; 1.4–8.8 μIU/mL) (Fig. 2). The child was referred to a pediatric endocrinology clinic. The diagnosis of severe acquired hypothyroidism was established, and L-Thyroxine 37.5 μg alternating with 50 μg orally daily was initiated. Thyroid antibodies and thyroid ultrasound scan were requested, and he was scheduled for follow-up after 2 weeks. Thyroid USS reported normal position and shape of the thyroid gland. Anti-thyroid peroxidase level was 213.0 IU/mL (N <34 IU/mL), and anti-thyroglobulin antibody level was 163.0 IU/mL (N <115 IU/mL) significantly high, supporting the diagnosis of Hashimoto’s hypothyroidism. Four weeks later, a repeated thyroid function test revealed TSH 0.8 μIU/mL and Free T4 was 44.9 pmol/L. Hence, the thyroxine dose was adjusted to 37.5 μg orally daily. After another 4 weeks, repeated TSH was 0.5 μIU/mL and Free T4 20 pmol/L. CBC showed resolving normocytic normochromic anemia with a HB level of 10.2 g/dL. He was continued on thyroxine 37.5 μg PO OD and advised regular follow-up. Six months later, his TSH normalized to 6.0 μIU/mL, Free T4: 17.6 pmol/L, and his HB was 10.1 g/dL. In view of the right torticollis, orthopedic consultation was obtained, and the family was reassured. The ophthalmologist assessed the child and diagnosed him with horizontal nystagmus, astigmatism, plus myopia of both eyes. He continued to receive multidisciplinary follow-up with the pediatric hematology, endocrinology, and ophthalmology teams.
During his regular follow-up, at age of 18 months, the child was more alert and interactive, his facial expression normalized, and he was able to walk supported. His height increased to the 25th centile.

**Discussion**

Autoimmune thyroiditis, known as chronic lymphocytic or Hashimoto thyroiditis, is the commonest cause of pediatric-acquired hypothyroidism [1], which is rarely presented under 3 years of age [2]. Hypothyroidism and anemia also cause nonspecific signs of disease, such as exhaustion, with a detrimental effect on one's quality of life. Anemia and hypothyroidism coexistence is not only difficult to diagnose, but can also indicate a causal association between thyroid disease and anemia [3]. Indeed, there are links between thyroid disease and anemia, which have been previously documented in experimental animal studies [4]. On the other hand, human data regarding the relationship between hematologic disorders and thyroid are limited. Anemia was frequently observed in adult patients with hypothyroidism. The nature of the anemia noted in adult patients was quite variable [5, 6]. The incidence of anemia in adult patients associated with hypothyroidism is reported to be between 21% and 100% [5, 6]. Adult hypothyroid patients were found to have a high rate of anemia. The type of anemia encountered by these patients has been very varied [5, 6]. Researchers discovered red cell defects and a decreased proliferative capacity of hematopoietic progenitor cells in patients with hyperthyroidism and hypothyroidism [7]. Currently, it is still unclear what pathological mechanisms connect thyroid function and erythropoiesis or how thyroid disease can contribute to anemia. Low thyroid function may be related to anemia through deficits in development of healthy erythrocytes in both subclinical and overt hypothyroidism. The mechanisms by which thyroid hormones and TSH can cause anemia are not completely understood [8]; T3, T4, and TSH could play a part in erythropoiesis [9].

Moreover, T3 and T4 are involved in control of hematopoiesis by affecting the proliferative ability of erythroid precursors [10]. T4 was found to facilitate the initiation and completion of HB protein chain synthesis and promote red blood cells’ production [11]. Furthermore, thyroid hormones could influence iron transport and consumption. TSH might affect hematopoiesis by binding to a functional TSH receptor found in erythrocytes and some extra-thyroidal tissues [7]. Moreover, iron deficiency, the most common cause of anemia, could reduce thyroid peroxidase activity, an iron-containing enzyme involved in thyroid function [12].

Chu et al. [13] examined 17 children and adolescents (excluding neonates) with hypothyroidism. Anemia was observed in 11 patients (65%). The red blood cells’ MCV was either macrocytic or normocytic. The serum thyroxine level did not correlate with HB. Anemia was observed

only in patients whose heights were below 3rd percentile, but they failed to have a similar correction to their weights. Patients who had anemia secondary to hypothyroidism responded well to thyroid hormone replacement therapy alone. In our case, detection of underlying etiology for normochromic normocytic anemia was challenging. The relationship between normochromic normocytic anemia and hypothyroidism in our patient was evident by excluding all other causes of normochromic normocytic anemia. Typical features of hypothyroidism (dullness, protruded tongue, delayed developmental milestones, and growth deceleration) and the dramatic improvement after starting L-Thyroxine therapy, with normalization of blood indices corresponding to normalization of thyroid function (Fig. 2), support the hypothesis that anemia and hypothyroidism were related.

The peculiarity of our case report was the early onset of autoimmune thyroiditis in our patient who was below 1 year of age, with severe hypothyroidism phenotype, associated with pallor and unexplained normochromic normocytic anemia. The age of presentation (below 1 year of age), the normal neonatal screening, and the normal serum level of repeated thyroid function at the age of 1 week made congenital hypothyroidism a remote possibility. Indeed, our patient showed growth deceleration, sleepy expression, dull-look, changes in the face habitus, delayed development milestones, social disinterest, and had constipation which raised the possibility of the diagnosis of hypothyroidism. Failure to relate the normochromic normocytic anemia to specific etiology apart from the possibility of transient erythroblastopenia of childhood and the rapid resolution of the anemia with improved thyroid function confirms the presence of anemia as sequelae to the acquired hypothyroidism.

We report this case to draw the attention of clinicians that despite regular neonatal screening for congenital hypothyroidism, extreme overt hypothyroidism due to autoimmune thyroiditis can develop early in life. Autoimmune thyroiditis was discovered in our patient early in his life, when thyroid hormones are essential for proper mental growth [14], necessitating close monitoring and potential cognitive evaluation to identify the outcome better and start appropriate interventions. Furthermore, we strongly recommend considering hypothyroidism in the differential diagnosis of cases of unexplained, persistent normochromic normocytic anemia. We believe that the association of disorders in the blood indices in cases of hypothyroidism might signal the severity of the condition.

Conclusions

While neonatal screening for congenital hypothyroidism is routine, extreme acquired hypothyroidism due to autoimmune thyroiditis may occur early in life, and clinicians should be aware of this possibility. Hypothyroidism can present in various ways, particularly with anemia, which can be the presenting symptom and the most prominent manifestation. Hypothyroidism can have a deceptive and multifaceted clinical appearance, especially with unexplained anemia. Hypothyroidism should be considered in the differential diagnosis of normocytic, normochromic anemia in infants who have a falloff in linear growth and present with normocytic, normochromic anemia of uncertain origin. Thyroxine replacement therapy alone can restore all clinical manifestations linked to hypothyroidism and anemia. Further studies are needed to determine the possible underlying mechanism of this association.
