INTRODUCTION

Spinal anesthesia provides a fast, profound, and symmetrical sensory and motor block of high quality in patients undergoing cesarean delivery (1, 2). The most common serious adverse effect of spinal anesthesia for cesarean delivery is hypotension, with a reported incidence greater than 80% (3).

A number of strategies for preventing hypotension have been investigated, because it may have detrimental maternal and neonatal effects. The use of lateral uterine displacement is routine procedure to prevent hypotension (4). Other strategies have included the use of intravenous fluid preload, gravity (Trendelenburg or leg rising), compression devices on the legs, and prophylactic vasopressors (1). However, no methods have proved satisfactory. Ephedrine is the most commonly used drug among the vasopressors.

The prophylactic administration of ephedrine by the intramuscular route is very controversial because its systemic absorption and peak effect are difficult to predict, thus, possibly resulting in rebound hypertension (5). The intravenous route may be more effective and controllable, although large doses are used; the incidence of hypotension was still high in some studies (6, 7).

Intravenous ephedrine given immediately after the induction of spinal anesthesia has been described (7, 8). Doses of 10-20-30 mg or 0.25 mg/kg were not effective in eliminating hypotension completely (7-10). Therefore, we designed a randomized, double-blinded study to determine efficacy and safety of 0.5 mg/kg intravenous ephedrine for preventing hypotension during spinal anesthesia for cesarean delivery.

MATERIALS AND METHODS

During the study period, 52 consecutive patients were identified suitable for the study. They were women, ASA status I or II, undergoing elective cesarean section under spinal anesthesia. Three had to be excluded because of hypertension, two refused to participate, and one was missed because of high workload. Written informed consent was obtained from each subject, and the study protocol was approved by the Human Ethics Committee of our medical school. Patients with pre-existing or pregnancy-induced hypertension, known cardiovascular or cerebrovascular disease, abnormal cardiotocography (CTG) tracing, or contraindications to spinal anesthesia were excluded. Randomization was based on a computer-generated code that was prepared at a remote site and sealed in opaque, sequentially numbered envelopes. The patients were randomly divided into two groups: ephedrine group (n=23) and control group (n=21). Intravenous preload of 15 mL/kg lactated Ringer’s solution was given. Shortly after the spinal injection, ephedrine 0.5 mg/kg or saline was injected intravenous for 60 sec. The mean of highest and lowest heart rate in the ephedrine group was higher than those of control group (P<0.05). There were significant lower incidences of hypotension and nausea and vomiting in the ephedrine group compared with the control group (8 [38.1%] vs. 18 [85.7%]; 4 [19%] vs. 12 [57.1%], respectively) (P<0.05). The first rescue ephedrine time in the ephedrine group was significantly longer (14.9 ± 7.1 min vs. 7.9 ± 5.4 min) than that of the control group (P<0.05). Neonatal outcome were similar between the study groups. These findings suggest, the prophylactic bolus dose of 0.5 mg/kg intravenous ephedrine given at the time of intrathecal block after a crystalloid fluid preload, plus rescue boluses reduce the incidence of hypotension.

The Effects of Intravenous Ephedrine During Spinal Anesthesia for Cesarean Delivery: A Randomized Controlled Trial

We designed a randomized, double-blinded study to determine efficacy and safety of 0.5 mg/kg intravenous ephedrine for the prevention of hypotension during spinal anesthesia for cesarean delivery. Patients were randomly allocated into two groups: ephedrine group (n=21) and control group (n=21). Intravenous preload of 15 mL/kg lactated Ringer’s solution was given. Shortly after the spinal injection, ephedrine 0.5 mg/kg or saline was injected intravenous for 60 sec. The mean of highest and lowest heart rate in the ephedrine group was higher than those of control group (P<0.05). There were significant lower incidences of hypotension and nausea and vomiting in the ephedrine group compared with the control group (8 [38.1%] vs. 18 [85.7%]); 4 [19%] vs. 12 [57.1%], respectively) (P<0.05). The first rescue ephedrine time in the ephedrine group was significantly longer (14.9 ± 7.1 min vs. 7.9 ± 5.4 min) than that of the control group (P<0.05). Neonatal outcome were similar between the study groups. These findings suggest, the prophylactic bolus dose of 0.5 mg/kg intravenous ephedrine given at the time of intrathecal block after a crystalloid fluid preload, plus rescue boluses reduce the incidence of hypotension.

WI, U.S.A.) as the mean of three successive measurements, 1 min apart and in the modified supine position with at least 15° of left lateral tilt. 18-gauge intravenous cannula was sited in the non-dominant hand and intravenous preload of 15 mL/kg lactated Ringer’s solution was given, within 15 min, after which the intravenous infusion was slowed to the minimum rate required to maintain vein patency.

Spinal anesthesia was administered with the patient in the right lateral position. After skin infiltration with lidocaine, a 25-gauge Whitacre needle was inserted at the L2-3 or L3-4 vertebral interspace and hyperbaric 0.5% bupivacaine 2 mL with fentanyl 10 μg was injected intrathecally. The patient was then immediately turned supine with left lateral tilt. Oxygen 4 L/min was given by nasal cannula until delivery.

Shortly after the spinal injection, ephedrine 0.5 mg/kg in the ephedrine group or saline in the control group was injected intravenously for 60 sec. All study medications were administered by an anesthetist not be involved in the care of the patient or collection of data. A second anesthetist, blind to identity of the study medication, managed the patient. The study period started at the time of intrathecal injection and ended when the umbilical cord was clamped. Systolic arterial pressure and heart rate were recorded at 1-min intervals. Fetal heart rate was monitored by using CTG continuously until delivery. The baseline SAP and HR, lowest and highest SAP and HR, nausea, vomiting, dizziness, and chest symptoms were recorded every minute. The first rescue ephedrine time, total doses of rescue ephedrine, and total dose of used ephedrine were also recorded. Upper sensory level of anesthesia was measured by assessing loss of pinprick discrimination at 10 min. All blocks extended to T5 or above, before surgery was allowed to start.

Hypotension was defined as 20% decrease in SAP from baseline. Hypertension was defined as 20% increase in SAP from baseline. Maternal bradycardia was defined as heart rate <60 beats/min and treated immediately by using intravenous atropine 0.5 mg. Tachycardia was defined as heart rate >120 beats/min. Hypotension was treated immediately by using rescue intravenous ephedrine 5 mg every minute until SAP returned to normal values (>80% of baseline value).

After delivery, Apgar scores were assessed at 1 and 5 min by the attending pediatrician. Arterial blood samples were taken from umbilical cord for blood-gas analysis within 2 min. All patients received oxytocin 20 units/L in crystalloid after delivery.

Prospective power analysis showed that a sample size of 20 patients per study group would have 80% power at the 5% significance level to detect a difference of 50% in the incidence of hypotension in the study group compared with control, assuming a baseline incidence of 80%, as reported in a published study of a similar patient group (10).

Data were presented as mean ± standard deviation, median (range), or percentage, as appropriate. Statistical analyses were performed Statistica 7.0. Software (Statsoft, Inc., Tulsa, AR, U.S.A.). Demographic parameters, delivery time, first rescue ephedrine time, umbilical arterial pH, SAP, and HR were compared with t-test. Changes over time in SAP and HR between and within the study groups, comparing values at each time point, were analyzed with repeated measures ANOVA followed by a post hoc Bonferroni test to identify significant differences. Doses of total rescue and used ephedrine, Apgar scores, and upper sensory level were compared with Mann-Whitney U test. Hypotension, hypertension, tachycardia, bradycardia and nausea and vomiting of the study groups were compared with χ² or Fisher’s exact test, as appropriate. A P value of <0.05 was considered significant.

**RESULTS**

Of 46 patients randomized, two in the both groups (n=21) had to be excluded from data analysis because of the protocol violations. In each study group, 21 patients completed the study protocol. There was no difference between the study groups with regard to the age, weight, height, and delivery time (P >0.05) (Table 1). All patients had adequate surgical anesthesia. The median upper sensory level 10 min after the intrathecal injection was T4 (T3-T5) for all the study groups.

![Fig. 1. Baseline, the lowest, and highest systolic arterial pressure (SAP) and heart rate (HR) of the study groups. Values are mean± SD. *P<0.05 vs. control group.](image-url)

**Table 1.** Patient characteristics

|                      | Ephedrine group (n=21) | Control group (n=21) |
|----------------------|------------------------|----------------------|
| Age (yr)             | 25.6±4.1               | 27.9±6.3             |
| Height (cm)          | 161.8±5.2              | 161.1±4.9            |
| Weight (kg)          | 70.9±7.7               | 68.8±6.9             |
| Upper sensory level (dermatome) | 14 (T3-T5)        | 14 (T3-T5)          |
| Spinal to delivery time (min) | 21.0±2.5               | 20.6±2.6             |

Values are mean± SD or median (min-max).
There was no significant difference in the SAP and HR values at baseline between the study groups ($P>0.05$). The mean highest and lowest HR in the ephedrine group was higher than those of control group ($P<0.05$). There were significant differences in mean lowest SAP between the study groups ($P<0.05$). The mean highest SAP in the ephedrine group was higher than that of control group, but this difference was not significant (Fig. 1). From 2 to 8 min, the mean SAPs in the control group were significantly lower than those of the ephedrine group ($P<0.05$) (Fig. 2). From 6 to 12 min, significant decreases of the mean SAP in the control group were observed as compared with baseline ($P<0.05$) (Fig. 2). From 4 to 8 min, the mean HR in the control group was significantly lower than that of the ephedrine group ($P<0.05$) (Fig. 3).

The incidences of hypotension, hypertension, tachycardia, bradycardia, nausea or vomiting, the total doses rescue and used ephedrine, and the first rescue ephedrine time are summarized in Table 2. There was significant lower incidences of hypotension in the ephedrine group compared with the control group (8 [38.1%] vs. 18 [85.7%]) ($P<0.05$). There was no difference in the ratio of hypertension between the study groups ($P>0.05$). The ratio of bradycardia in the control group was significantly higher than that of the ephedrine group (14.3% vs. 0%; $P<0.05$). There were significant decrease total doses of rescue ephedrine required in the ephedrine group ($P<0.05$) (Table 2). Total doses of used ephedrine in the ephedrine group were significant higher than that of control group. The first rescue ephedrine time in the ephedrine group was significantly longer (14.9 ± 7.1 min vs. 7.9 ± 5.4 min) than that of the control group ($P<0.05$) (Table 2).

No abnormal CTG tracing was observed until delivery. Analysis of neonatal data showed no differences between the study groups. No Apgar scores were below 7 at 1 min or 5 min. Umbilical arterial pH were similar between the study groups ($P>0.05$). There was no pH <7.2 in both groups (Table 3).

**DISCUSSION**

This is the first report to our knowledge to investigate the effect of intravenous ephedrine given according to maternal weight dose of 0.5 mg/kg after the induction of spinal anesthesia for cesarean section to prevent hypotension related to spinal anesthesia. Our findings demonstrated that prophylactic intravenous ephedrine during spinal anesthesia for cesare-
an section can prevent hypotension without significant mater-

nial tachycardia or hypertension, and also it increases the first

reactive ephedrine time and decreases the ratio of nausea and

vomiting. Umbilical arterial pH and Apgar scores were not

influenced by hypotension or ephedrine medication.

The incidence of hypotension during spinal anesthesia for

cesarean section is reported to be as high as 80%, despite fluid

preload, lateral uterine displacement and use of vasopressor

agents (11). In the anesthesia practice, prevention and man-

agement of hypotension related to spinal anesthesia remains

a difficult problem and there was no consensus on its optimal

management.

Phenylephrine, \(\alpha\)-adrenergic agonist whose action would

be expected to counteract the decrease in systemic vascular

resistance induced by spinal anesthesia (12). Phenylephrine

can be used for the prevention and treatment of maternal hy-

potension (13-15) but a reduction of fetal oxygenation due

to uterine vasoconstriction has been observed in animals (16).

It may cause maternal bradycardia (14, 17). Loughrey et al.

(18) compared intravenous bolus of ephedrine and phenyle-

phrine combination with ephedrine alone. They found the

combination of ephedrine and phenylephrine given as an in-

travenous bolus was not superior regarding to the incidence

of hypotension, maternal side effects, or umbilical blood gases

when administered as a prophylactic bolus followed by res-

cue boluses and compared to ephedrine alone.

Ephedrine, an indirectly acting sympathomimetic amine, is

probably the vasopressor of choice in obstetric anesthesia.

Although ephedrine has mixed \(\alpha\) - and \(\beta\)-adrenoceptor ac-

tivity, it maintains arterial pressure mainly by increases in car-

diac output (CO) and heart rate as a result of its predominant

activity on \(\beta 1\)-adrenoceptors (19). Variable intravenous in-

fuions of ephedrine appear to be successful (14, 20-22). Kee et

al. (10) investigated the efficacy and optimum dose of intra-

venous ephedrine for prevention of hypotension during spinal

anesthesia for cesarean delivery. They compared the effect of

ehedrine 10, 20, or 30 mg intravenous for the prevention

of hypotension. They found that a bolus dose of 30 mg in-

travenous ephedrine was required to reduce the incidence of

hypotension during spinal anesthesia for cesarean delivery. They

concluded that although the incidence of hypotension was

reduced to 35% in the patients who received ephedrine 30

mg compared with the control rate of 95%, this was at the

expense of an increased incidence of hypertension, which

occurred in 45% of the patients. They suggested that 30-mg

intravenous ephedrine may not be suitable in some patients

such as those with cardiovascular or cerebrovascular disease.

Compared with the study of Kee et al. (10), the incidence of

reactive hypertension is lower in our study (45% vs. 28.6%).

Duration of ephedrine administration in the study of Kee et

al. was 30 sec, however, in our study; it was 60 sec. Decreased

ratio of reactive hypertension in the ephedrine group in our

study may result from the longer duration of ephedrine ad-

ministration. Particularly if sympathetic block level is low,
in patients who received intravenous ephedrine compared with the control groups. We found no significant difference in neither Apgar scores nor umbilical arterial blood gases data between the study groups, despite a difference in the incidence of hypotension, probably reflecting the early recognition and restoration of hypotension with rescue ephedrine.

Although mean highest HR in the ephedrine group was higher, we found no difference in ratio of tachycardia between the study groups. This could be explained by both the effect of “rescue” ephedrine and baroreceptor-mediated reflex increases in heart rate in patients who became hypotensive. In addition, atropine was applied for bradycardia in the control group.

These findings suggest, the prophylactic bolus dose of 0.5 mg/kg intravenous ephedrine given at the time of intrathecal block after a crystalloid fluid preload, plus rescue boluses reduce the incidence of hypotension. It has not been shown to eliminate the need to treat maternal hypotension during spinal anesthesia for elective cesarean delivery compared to intravenous rescue boluses alone.
