We have observed signatures of resonant tunneling in an Al three-junction qubit, inductively coupled to a Nb LC tank circuit. The resonant properties of the tank oscillator are sensitive to the effective susceptibility (or inductance) of the qubit, which changes drastically as its flux states pass through degeneracy. The tunneling amplitude is estimated from the data. We find good agreement with the theoretical predictions in the regime of their validity.

PACS numbers: 85.25.Cp, 85.25.Dq, 84.37.+q, 03.67.Lx

Several groups, using different devices, have by now established that superconductors can behave as macroscopic quantum objects.1–3 These are natural candidates for a qubit, the building block of a quantum computer.

Qubits are effectively two-level systems with time-dependent parameters. One of them is a superconducting loop with low inductance L, including three Josephson junctions (a 3JJ qubit).4 Its potential energy, \( U = \sum_{j=1}^{3} E_{J_{j}}(\phi_{j}) \), depends on the Josephson phase differences \( \phi_{j} \) across the junctions. Due to flux quantization \( \sum_{j=1}^{3} \phi_{j} = 2\pi \Phi_{x}/\Phi_{0} \) (with \( \Phi_{x} \) the external magnetic flux and \( \Phi_{0} = h/2e \) the flux quantum), only two \( \phi_{j} \)'s are independent.

For suitable parameters, \( U(\phi_{1},\phi_{2}) \) has two minima corresponding to qubit states \( \Psi^{1} \) and \( \Psi^{2} \), carrying opposite supercurrents around the loop. These become degenerate for \( \Phi_{x} = \frac{\Phi_{0}}{2} \). The Coulomb energy \( E_{C} \approx e^{2}/2C \), with \( C \) the capacitance of junction 1) introduces quantum uncertainty in the \( \phi_{j} \). Hence, near degeneracy the system can tunnel between the two potential minima. (Since \( E_{C} \ll E_{J} \approx E_{J_{1}} \), we deal with a flux qubit; \( E_{C} \gg E_{J} \) yields a charge qubit. Coherent tunneling was demonstrated in both.)

In the basis \( \{ \Psi^{1},\Psi^{2} \} \) and near \( \Phi_{x} = \frac{\Phi_{0}}{2} \), the qubit can be described by the Hamiltonian

\[
H(t) = -\epsilon(t) \sigma_{z} - \Delta \sigma_{x};
\]

\( \Delta \) is the tunneling amplitude. At bias \( \epsilon = 0 \) the two lowest energy levels of the qubit anticross [Fig. 1(a)], with a gap of \( 2\Delta \). Increasing \( \epsilon \) slowly enough, the qubit can adiabatically transform from \( \Psi^{1} \) to \( \Psi^{2} \), staying in the ground state \( E_{\pm} \). Since \( dE_{\pm}/d\Phi_{x} \) is the persistent loop current, the curvature \( d^{2}E_{\pm}/d\Phi_{x}^{2} \) is related to the qubit’s susceptibility. Hence, near degeneracy the latter will have a peak, with a width given by \( |\epsilon| \lesssim \Delta \).5 We present data demonstrating such behavior in an Al 3JJ qubit.

Our technique is similar to rf-SQUID readout6,7 The qubit loop is inductively coupled to a parallel resonant tank circuit [Fig. 1(b)]. The tank is fed a monochro-

matic rf signal at its resonant frequency \( \omega_{T} \). Then both amplitude \( v \) and phase shift \( \chi \) (with respect to the bias current \( I_{0} \)) of the tank voltage will strongly depend on (A) the shift in resonant frequency due to the change of the effective qubit inductance by the tank flux, and (B) losses caused by field-induced transitions between the two qubit states. Thus, the tank both applies the probing field to the qubit, and detects its response.

The output signal depends on the tank’s quality factor \( Q \). Using superconducting coil, values as high as \( Q \sim 10^{3} \) can be obtained, leading to high readout sensitivity, e.g., in rf-SQUID magnetometers.8 Such a tank can therefore be used to probe phase qubits.3 For small \( L \), the results are summarized by5

\[
v = I_{0}\omega_{T}L_{T}Q/\sqrt{1 + (2Q\xi)^{2}};
\]
tor in state curvature is \( f \) where \( \phi \) is the lower to the upper curve (at \( f_x = 0 \)) the driving-voltage amplitude \( V_{dc} \equiv I_0 \omega_{LT} L T Q \) takes values 0.5, 1.0, 1.5, 1.9, 2.9, 3.5, 3.9 \( \mu \)V. Inset: theoretical curves for \( \Delta / h \approx 650 \) MHz, and \( I_0 \approx 0.07, 0.13, 0.20, 0.26, 0.39, 0.47, 0.53 \) nA.

\[
\tan \chi = 2Q \xi, \tag{3}
\]

\[
\xi(v, f_x) = \frac{k^2 L}{2 \Phi_0^2} \int_0^{2\pi} d\phi \cos^2 \phi \frac{d^2 E_-}{df^2}(f), \tag{4}
\]

\[
f = f_x + \frac{M v}{\omega_T L T \Phi_0} \sin \phi, \tag{5}
\]

where \( f_x = \Phi_x / \Phi_0 - \frac{1}{2}, I_0 \) is the bias-current amplitude, and \( k = M / \sqrt{L T} \) is the tank–qubit coupling coefficient, with \( M (L_T) \) the mutual (tank) inductance. The ground-state curvature is

\[
d^2E_- \over df^2 = - \frac{E^2_\lambda \Delta^2 \lambda^2}{(E^2_\lambda f^2 + \Delta^2)^{3/2}}, \tag{6}
\]

where \( \lambda(\delta, g) \) (with \( g = E_\lambda / E_C \)) is the conversion factor in \( \epsilon = E_\lambda f. \) If \( I_0 \) vanishes, \( \xi = \frac{1}{2} k^2 L d^2 E_- / d\Phi_0^2 \) becomes an external parameter accounting for the qubit susceptibility coupled to the tank. For finite \( I_0 \), this has to be averaged over a bias cycle \( 0 < \phi < 2\pi \). The resulting integral (4) turns out to involve a weight \( \cos^2 \phi \), since the effective time-dependent coupling is \((k f)^2\) [cf. the \( \phi \)-derivative of Eq. (5)], proportional to the square of the voltage the tank induces in the qubit. The resulting equations are coupled and nonlinear, but readily solved numerically.

For the tank, we prepared a square-shape Nb pancake coil on an oxidized Si substrate. The line width of the 20 windings was 2 \( \mu \)m, with a 2 \( \mu \)m spacing. Predefined alignment marks allow placing a qubit in the center. For flexibility, only the coil was made lithographically; an external capacitance \( C_f \) is used to change \( \omega_T \) in the range 5–35 MHz. For the selected tank \((L_T \approx 50 \text{ nH}, C_T \approx 470 \text{ pF})\), we obtained \( \omega_T / 2\pi = 32.675 \text{ MHz} \) and \( Q \approx 725 \) from the voltage–frequency characteristic.

The 3JJ qubit structure was manufactured out of Al by conventional shadow evaporation. The area of two of the junctions was estimated using electron microscopy as \( 190 \times 650 \text{ nm}^2 \) while one is smaller, so that \( \alpha = E_{13}/E_{11,2} \approx 0.8 \). The critical current was determined by measuring an rf-SQUID prepared on the same chip\(^7\) as \( I_c = 2 e E_\lambda / h \approx 380 \text{ nA} \). With \( E_C / h \approx 3 \text{ GHz} \), one finds \( g \approx 60 \text{ and } \lambda \approx -4.4 \). The loop area was \( 90 \mu\text{m}^2 \), with \( L = 38 \text{ pF} \). We measured \( v \) by a three-stage cryogenic amplifier, placed at \( \approx 2 \text{ K} \) and based on commercial pseudomorphic high electron mobility transistors. It was slightly modified from the version in Ref. 12 to decrease its back-action on the qubit. The input-voltage noise was \( < 0.6 \text{ nV}/\sqrt{\text{Hz}} \) in the range 1–35 MHz. The noise temperature was \( \approx 300 \text{ mK} \) at 32 MHz. The effective qubit temperature due to the amplifier’s back-action should be considerably lower because of the small \( k \approx 2 \cdot 10^{-2} \).

The \( \chi(f_x) \) curves measured at various \( I_0 \) and a mixing-chamber temperature \( T = 10 \text{ mK} \) are shown in Fig. 2. The narrow dip at \( f_x = 0 \) directly corresponds to the
one in Eq. (6), in line with the qualitative picture below Eq. (1). With device parameters as above, all quantities in Eqs. (2)–(6) are known, but $\Delta$ only in principle: its exponential sensitivity to $\alpha$ and especially $g$ makes it notoriously hard to calculate a priori. Hence, it is treated as a free parameter; calculated curves for the best fit $\Delta/h = 650$ MHz are shown in the inset. For the largest $I_0$ the experimental and theoretical curves disagree, for the rapid change of $\Phi_0$ then leads to Landau–Zener transitions\textsuperscript{13,14} suppressing the dip.

The $T$-dependence of $\chi$ is shown in Fig. 3. For increasing $T$ the dip’s amplitude decreases while, strikingly, its width is unchanged [Fig. 3(c)]. Both are a simple manifestation of the Hamiltonian (1) yielding $\langle \sigma_z \rangle = (\epsilon/\Omega) \times \tanh(\Omega/k_B T)$,\textsuperscript{15} $\Omega = \sqrt{\epsilon^2 + \Delta^2}$. This result of equilibrium statistics of course assumes that the $T$-dependence of $\epsilon(t)$ is adiabatic. However, it does remain valid if the full (Liouville) evolution operator of the qubit would contain standard Bloch-type relaxation and dephasing terms (which indeed are not probed\textsuperscript{3} in addition to the Hamiltonian dynamics (1), since the fluctuation–dissipation theorem guarantees that such terms do not affect equilibrium properties. Normalized dip amplitudes are shown vs $T$ in Fig. 3(b) together with $\tanh(\Delta/k_B T)$, for $\Delta/h = 650$ MHz independently obtained above from the low-$T$ width. The good agreement strongly supports our interpretation, and is consistent with $\Delta$ being $T$-independent in the relevant range.\textsuperscript{16} Of course, for higher $T$ the dip will wash out; we observe a width $\propto T^3$ above a crossover temperature $\approx 225$ mK. For $T$ of this order, deviations from the two-state model can be expected, especially for $f_x \neq 0$. This behavior outside the qubit regime has not been pursued.

In conclusion, we have observed resonant tunneling in a macroscopic superconducting system, containing an Al flux qubit and a Nb tank circuit. The latter played dual control and readout roles. The impedance readout technique allows direct characterization of some of the qubit’s quantum properties, \textit{without} using spectroscopy.\textsuperscript{2,3} In a range $50$–$200$ mK, the \textit{effective} qubit temperature has been verified [Fig. 3(b)] to be the same as the mixing chamber’s (after $\Delta$ has been determined at low $T$), which is often difficult to confirm independently.

MHSa and AMvDB are grateful to A.Yu. Smirnov and A.M. Zagoskin for fruitful discussions, and to P.C.E. Stamp for the remark on effective thermometry. MG wants to acknowledge partial support by the Slovak Grant Agency VEGA (Grant No. 1/9177/02).

\item A minus sign is missing in Eq. (17) of Ref. 5.
\item Let us rectify the discussion of $\lambda$, Eq. (12) in Ref. 5. In Eq. (1) of Ref. 2, $\epsilon$ is expressed in terms of the persistent current (subsequently given numerically for their sample parameters) instead of $E_J$, which implicitly incorporates $\lambda$. In T.P. Orlando et al., Phys. Rev. B \textbf{60}, 15398 (1999), the flux-energy conversion is carried out in Eq. (32) and Appendix B. Our $\lambda$ differs from their $\gamma_1/E_J$ only in an $O(g^{1/2})$ correction [taken into account below our Eq. (6)], plus an overall sign immaterial for $\lambda$. This correction decreasing (here by $\sim 9\%$) may be small, but it has a clear interpretation: as $f_x$ increases, the upper well, ultimately losing classical stability, becomes softer. Hence, its local zero-point energy decreases, slightly counteracting the rise of the potential minimum.

\item Using this simple tanh law also for the net qubit response $\propto \partial_t \langle \sigma_z \rangle$ accounts for the following subtlety. While our method is quasi-equilibrium, \textit{on the scale of one bias cycle} $\sim \omega_c^{-1}$ relaxation is slow. Hence, in the finite-$T$ generalization, flux derivatives such as in Eq. (6) become adiabatic rather than isothermal. For finite $T$ and $v$, the problem is essentially nonequilibrium and outside our scope.
