BACKGROUND: Traffic-related air pollution is related with asthma, and this association may be modified by genetic factors.

OBJECTIVES: We investigated the role of genetic polymorphisms potentially modifying the association between home outdoor levels of modeled nitrogen dioxide and asthma.

METHODS: Adults from 13 cities of the European Community Respiratory Health Survey (ECRHS II) were included (n = 2,928), for whom both DNA and outdoor NO2 estimates were available. Home addresses were geocoded and linked to modeled outdoor NO2 estimates, as a marker of local traffic-related pollution. We examined asthma prevalence and evaluated polymorphisms in genes involved in oxidative stress pathways [glutathione S-transferases M1 (GSTM1), T1 (GSTT1), and P1 (GSTP1) and NAD(P)H:quinone oxidoreductase (NQO1)], inflammatory response [tumor necrosis factor α (TNFA)], immune response [Toll-like receptor 4 (TLR4)], and airway reactivity [adrenergic receptor β2 (ADRB2)].

RESULTS: The association between modeled NO2 and asthma prevalence was significant for carriers of the most common genotypes of NQO1 rs2917666 [odds ratio (OR) = 1.54; 95% confidence interval (CI), 1.10–2.24], TNFA rs2844484 (OR = 2.02; 95% CI, 1.30–3.27). For new-onset asthma, the effect of NO2 was significant for the most common genotype of NQO1 rs2917666 (OR = 1.52; 95% CI, 1.09–2.16). A significant interaction was found between rs2917666 and NO2 for asthma prevalence (p = 0.02) and new-onset asthma (p = 0.04).

CONCLUSIONS: Genetic polymorphisms in the NQO1 gene are related to asthma susceptibility among persons exposed to local traffic-related air pollution. This points to the importance of antioxidant pathways in the protection against the effects of air pollution on asthma.

KEY WORDS: air pollution, asthma, gene polymorphisms, genetics, nitrogen dioxide, oxidative stress, traffic pollution. Environ Health Perspect 117:1919–1924 (2009). doi:10.1289/ehp.0900589 available via http://dx.doi.org/ [Online 23 July 2009]

Asthma is a complex disease with both genetic and environmental components. The interaction between genetic predisposition and environmental factors is likely to have an important role in the etiology and progression of the disease. However, only few studies have addressed gene–environment interactions in asthma (Castro-Giner et al. 2006; London 2007; Yang et al. 2008).

Air pollution contributes to the development of asthma (Brauer et al. 2007; Gehring et al. 2002; Jacquemin et al. 2009; McConnell et al. 2006; Modig et al. 2006) and asthma exacerbations (D’Amato et al. 2005; Heinrich and Wichmann 2004; Künzli et al. 2000; Nel et al. 2005). Traffic-related pollutants such as particulate matter, nitrogen dioxide, and ozone are strong oxidants (D’Amato et al. 2005), leading to the production of reactive oxygen species (ROS). Oxidative stress triggers the inflammatory response and cytokine production (Kelly 2003; Nel 2005). It is plausible that genetic variants involved in inflammation and protection against ROS may influence the response to air pollutants. Polymorphisms in oxidative stress genes NAD(P)H:quinone oxidoreductase (NQO1, GeneID 1728 [Entrez Gene 2008]), glutathione S-transferases M1 (GSTM1, GeneID 2944 [Entrez Gene 2008]), and P1 (GSTP1, GeneID 2950 [Entrez Gene 2008]) have been associated with a decrease on pulmonary function (Bergamaschi et al. 2001; Romieu et al. 2004; Yang et al. 2005) and asthma and wheezing (Li et al. 2006) in relation to O3 and sulfur dioxide exposure. A recent study using nitrogen oxides (NOx) as an indicator for local traffic air pollution has reported interaction effects between GSTP1 polymorphisms and NOx on allergic sensitization to common allergens in children at 4 years of age. This interaction was more pronounced in carriers of TNFA –308 GA or AA genotype (Melén et al. 2008). Toll-like receptor 4 (TLR4, GeneID 7099 [Entrez Gene 2008]), implicated in innate immunity and endotoxin responsiveness, is also a candidate to be involved in air pollution susceptibility (Romieu et al. 2008; Saxon and Díaz-Sanchez 2005; Yang et al. 2008). In mouse models, lung hyperpermeability induced by O3 has been linked to the chromosome region containing the TLR4 gene (Kleeberger et al. 2000, 2001). Another plausible candidate gene to modify the effects of air pollution is adrenergic receptor β2 (ADRB2, GeneID 154 [Entrez Gene 2008]). It has been shown that polymorphisms in this gene interact with environmental tobacco smoke in children (Wang et al. 2008; Zhang et al. 2007) and cigarette smoke in adults (Joos et al. 2003; Litonjua et al. 2004; Wang et al. 2001). However, a previous study evaluating the combined effects of air pollutants and ADRB2 in children did not report significant findings (Melén et al. 2008).

To date, evidence for gene–air pollution interactions on asthma have been reported only in children (Melén et al. 2008; Yang...
Susceptibility to air pollution in early life may biologically differ from adulthood (Salam et al. 2008). Previous analysis on the European Community Respiratory Health Survey (ECRHS) reported that traffic-related pollution (using estimates of modeled NO$_2$ exposure) was positively associated with new-onset asthma in adults (Jacquemin et al. 2009). The aim of the present study was to identify interactions between genes and traffic-related pollution on asthma incidence and prevalence in a large population-based cohort (ECRHS) of adults. For this purpose, we evaluated previously reported candidate genes that have a role in oxidative stress (GSTM1, glutathione S-transferase T1 [GSTT1, GeneID 2952 (Entrez Gene 2008)], GSTP1, and NQO1), inflammatory response (TNFA), innate immunity (TLR4), and airway reactivity (ADRB2).

### Materials and Methods

**Study population.** The methodology of ECRHS has been described elsewhere (Burney et al. 1994; ECRHS II Steering Committee 2002). Briefly, the ECRHS is a random population-based multicenter cohort of subjects 20–44 years of age at the time of recruitment (1990; ECRHS I) and then followed approximately 10 years later in ECRHS II (median length of follow-up, 8.9 years). In a first step of ECRHS I, random recruited subjects were contacted to complete a short questionnaire on respiratory symptoms. In a second step, a 20% random sample of participants was recontacted, completed a long questionnaire, and underwent some exams. A complementary sample of subjects with asthma symptoms at recruitment was also included in the study. Ethical approval was obtained for each center from the appropriate institutional ethics committee, and written consent was obtained from each participant.

For ECRHS II, modeled NO$_2$ concentrations were assigned to a total of 5,470 participants in the 20 centers for which modeled air pollution was available. Genotyping was performed in 5,665 individuals from 19 centers, for which NO$_2$ was measured for 2,920 participants in 13 centers: Sweden (Umeå and Uppsala), United Kingdom (Ipswich and Norwich), Spain (Albacete, Barcelona, Huelva, Galdakao, and Oviedo), Germany (Erfurt), France (Paris and Grenoble), and Belgium (Antwerp). For the present analysis, we excluded subjects from the symptomatic sample who did not report asthma in ECRHS II, leading to a final sample size of 2,577. No major differences were observed between the complete sample with estimated NO$_2$, the subsample with DNA, and the subsample with both DNA and NO$_2$ [see Supplemental Material, Table 1 (doi:10.1289/ehp.0900589.S1 via http://dx.doi.org)].

Subjects included in our analysis could be considered as mainly of European–Caucasian origin. The prevalence of asthma was based on a positive response to either of two questions in ECRHS II: attack of asthma during the last 12 months or current use of asthma medication. New-onset (incident) of asthma was defined as reporting asthma (either attack of asthma in preceding 12 months or current medication for asthma) in ECRHS II (follow-up) excluding people who reported asthma (same definition as above) on a history of asthma in ECRHS I (baseline). Persistent asthma was defined as reporting asthma (either attack of asthma in preceding 12 months or current medication for asthma) in both surveys.

We evaluated the robustness of our results with other definitions of asthma: ever asthma, defined as a positive response to “have you ever had asthma?” and physician-diagnosed asthma, defined as a positive response to “have you ever had asthma diagnosed by a doctor?” Participants also underwent a bronchial challenge with methacholine chloride administered by Mefar aerosol dosimeters (Mefar, Bovezzo, Italy). Bronchial hyperresponsiveness was defined as a 20% fall in forced expiratory volume in 1 s (FEV$_1$) from the highest FEV$_1$ postdiluent during methacholine challenge with an accumulated dose of 1 mg (Burney et al. 1994; Chinn et al. 1997). Specific IgE levels to house dust mite, cat, timothy grass, and Cladosporium herbarum fungus were measured with the Pharmacia CAP system (Pharmacare Diagnostics, Uppsala, Sweden). Atopy was defined as sensitization (IgE levels > 0.35 kU/L) to any allergen.

**Modeled NO$_2$ concentrations.** NO$_2$ has been widely used as a marker of local traffic-related air pollution (Emenius et al. 2003; Forastiere et al. 2006; Jacquemin et al. 2009; Modig et al. 2006; Morgenstern et al. 2008). NO$_2$ measurements substantially differ within cities because they capture differences in exposure due to different proximities to traffic arteries. Details on modeling of NO$_2$ concentrations are described in the Supplemental Material (doi:10.1289/ehp.0900589.S1). Briefly, as part of the Air Pollution Modelling for Support to Policy on Health and Environmental Risk in Europe project (APMoSPHERE 2007), 1-km-resolution emission maps were developed.
The NO\textsubscript{x} emission map was used as the basis for modeling NO\textsubscript{2} concentrations using focal sum techniques in a global information system model. The NO\textsubscript{2} at the place of residence for each subject was then obtained by intersecting the point locations of their residence with the air pollution map.

**DNA extraction and genotype characterization.** Polymorphisms of the genes GSTM1, GSTT1, and GSTP1 were selected according to functional evidence from existing literature. For the genes NQO1, TNFA, TLR4, and ADRB2, we selected tag single-nucleotide polymorphisms (SNPs) in the gene region, 10 kb upstream from the 5’ untranslated region (UTR), and 10 kb downstream from 3’ UTR. Polymorphisms are listed in Table 1.

DNA was extracted from blood cells for samples using a commercially available kit (Puregene, Gentra Inc., MN, USA). The DNA bank was built and maintained at Helmholtz Zentrum München in Germany. Genotyping was performed at the Centre for Genomic Regulation in the Barcelona Node of the Centro Nacional de Genotipado (2009) in Spain. GSTM1 and GSTT1 genotypes were determined using polymerase chain reaction method and GSTP1 polymorphism by specific pyrosequencing assay. Genotyping for NQO1, TNFA, and TLR4 polymorphisms was performed using the SNPlex platform (Applied Biosystems, Foster City, CA, USA). The average genotyping rate was 98%.

**Statistical analysis.** The statistical analyses were performed using logistic regression implemented in the SNPassoc (version 1.5) (Gonzalez et al. 2007) package in R (version 2.6.1: R Foundation for Statistical Computing, Vienna, Austria). Generalized additive models (GAMs) were used to evaluate dose–response relationships with NO\textsubscript{2}. Logistic models and GAMs were adjusted for center, sex, age, environmental tobacco smoke, and smoking status. Multicollinearity interactions were assessed using likelihood-ratio test comparing models with additive term and interaction term. Heterogeneity was evaluated using the Mantel–Haenszel method under fixed-effects model with the R library rmeta package (version 2.14). Logistic mixed-effects models allowed the evaluation of a random effect of the variable center. These models were also adjusted for the previously described covariates.

We tested deviations of genotype frequencies from Hardy–Weinberg equilibrium (HWE) (Wigginton et al. 2005) in the randomly selected population. To check the independence of the polymorphisms, we estimated the correlation ($R^2$) and linkage disequilibrium coefficient ($D'$). Haplotypes were estimated using the haplo.em function from the haplo.stats package (version 1.3.8) (Schaid et al. 2002). Population stratification was assessed with the analysis of 26 unlinked markers [see Supplemental Material, Table 2 (doi:10.1289/ehp.0900589.S1)] using two different methods. First, the genomic control approach (Devlin and Roeder 1999) showed a minimal effect [inflation factor ($\hat{\lambda}$) = 1.06]. Second, principal component analysis using the EIGENSTRAT method (version 1.01) (Price et al. 2006) showed no evidence of population stratification [see Supplemental Material, Figure 1 (doi:10.1289/ehp.0900589.S1)].

Additional information on material and methods can be found in the Supplemental Material (doi:10.1289/ehp.0900589.S1).

**Results**

Table 2 lists population characteristics. The prevalence of current asthma in this sample was 12.7% ($n = 327$). Compared with subjects without asthma, asthmatics more often were women, were younger, reported less smoking, and had lower percentage of predicted lung function. Distribution of NO\textsubscript{2} was similar to the previously reported for the whole population (Jaccquemin et al. 2009) [see Supplemental Material, Table 3 (doi:10.1289/ehp.0900589.S1)]. The multivariate analysis of NO\textsubscript{2} and prevalence of asthma indicates a small but not significant increase in asthma for each 10-µg/m\textsuperscript{3} increase in NO\textsubscript{2} [odds ratio (OR) = 1.19; 95% confidence interval (CI), 0.97–1.47]. We observed departure from the HWE for GSTP1 rs16951 ($p < 0.01$). Allele distribution by center was heterogeneous for TNFA rs2844484 and TNFA rs909253 variants ($p < 0.01$).

For each genetic polymorphism, we evaluated the association between NO\textsubscript{2} (per 10-µg/m\textsuperscript{3} increase) and asthma prevalence separately for carriers of the minor allele (either homozygous or heterozygous) and for the subjects homozygous for the major allele (Table 1). We found no statistically significant associations between NO\textsubscript{2} and asthma for any of the genotypes of GSTM1, GSTT1, GSTP1, TLR4, and ADRB2 genes. The association between prevalence of asthma and NO\textsubscript{2} was significant for subjects homozygous for the major allele of NQO1 rs2917666 (OR = 1.54; 95% CI, 1.10–2.24) and for TNFA rs2844484 (OR = 2.02; 95% CI, 1.30–3.27). A test for interaction between these polymorphisms and NO\textsubscript{2} was significant only for NQO1 rs2917666 ($p$-value for interaction = 0.02). Analysis using GAM (Figure 1) indicated a significant linear increase in prevalence for homozygotes of the most prevalent alleles in NQO1 rs2917666 ($p = 0.02$) and no increase for the G/C and G/G genotypes.

We further performed the haplotype analysis for the three SNPs of NQO1 (rs10517, rs1800566, and rs2917666) in relation to NO\textsubscript{2} exposure and prevalence of asthma (Table 3). In this analysis, we provide Figure 1. Spline graphics using GAM for the association between NO\textsubscript{2} and current asthma, stratified by NQO1 rs2917666 genotypes. (A) C/C carriers. (B) G/C or G/G carriers. Dashed lines indicate 95% CI.

Table 2. Population characteristics at follow-up (ECRHS II) for subjects with both DNA and assigned levels of NO\textsubscript{2}.

|                | All          | No asthma   | Asthma        | p-Value |
|----------------|--------------|-------------|---------------|---------|
| Subjects [no.]| 2,577        | 2,253       | 327           |         |
| Females [no. (%)] | 1,345 (52.2) | 1,154 (51.3)| 191 (58.4)    | 0.02    |
| Age [years (mean ± SD)] | 43.03 ± 7.3  | 43.2 ± 7.2  | 41.83 ± 7.2   | 0.001   |
| Smoking status [no. (%)] | | | | |
| Never          | 1,130 (44)   | 969 (43.1)  | 161 (49.2)    | —       |
| Former         | 714 (27.8)   | 624 (27.8)  | 90 (27.5)     | —       |
| Current        | 729 (28.3)   | 653 (29.1)  | 76 (23.2)     | 0.05    |
| Same house during follow-up [no. (%)] | 1,348 (52.3) | 1,192 (53.0) | 156 (47.7) | 0.08    |
| Percent predicted FEV\textsubscript{i} (mean ± SD) | 106.81 ± 15.2 | 108.06 ± 13.9 | 95.58 ± 18.2 | < 0.001 |
estimates for exposure among subjects within combinations of SNPs. Linkage disequilibrium was weak between some of the NQO1 SNPs (D' = 0.97, r² = 0.03, and p < 0.01 between rs10517 and rs1800566; D' = 0.86, r² = 0.21, and p < 0.01 between rs10517 and rs2917666; D' = 0.59, r² = 0.53, and p < 0.01 between rs1800566 and rs2917666). The association between asthma prevalence and NO₂ was significant for the most prevalent haplotype, composed of the three major alleles of each SNP (OR = 1.23; 95% CI, 1.03–1.48). This was the only haplotype containing the C allele of rs2917666, which showed a significant interaction with NO₂ in the single SNP analysis. We observed no significant associations among carriers of the other haplotypes (Table 3).

We also analyzed longitudinal data to evaluate the effect of NO₂ on new-onset asthma. We observed a significant association between new-onset asthma and NO₂ levels for the 120 subjects who developed asthma during the follow-up period (OR = 1.52; 95% CI, 1.09–2.16). Subjects homozygous for the NQO1 rs291766 C allele were at greater risk (p-value for interaction = 0.04) for developing asthma [OR = 2.02; 95% CI, 1.16–3.73] compared with those with CG/GG genotypes (OR = 1.26; 95% CI, 0.83–1.99).

We restricted the analysis to those subjects who lived in the same home during follow-up (n = 1,348) to reduce exposure misclassification. Compared with subjects who changed homes, this group had an increased risk for main effects of exposure to NO₂ on asthma prevalence (movers: OR = 1.64; 95% CI, 1.08–2.53; nonmovers: OR = 1.02; 95% CI, 0.80–1.31; p-value for interaction = 0.03), whereas the effect on new-onset asthma was not different between movers and nonmovers (movers: OR = 1.48; 95% CI, 0.83–2.74; nonmovers: OR = 1.59; 95% CI, 1.05–2.52; p-value for interaction = 0.81). CC carriers of NQO1 rs291766 living in the same home during follow-up had an increased risk for prevalence (OR = 2.42; 95% CI, 1.19–5.24) and new-onset asthma (OR = 2.89; 95% CI, 1.02–9.46).

In a sensitivity analysis, we also evaluated our findings of interaction between NQO1 rs291766 and NO₂ for other asthma definitions and asthma-related phenotypes [see Supplemental Material, Table 4 (doi:10.1289/ehp.0900589.S1)]. Interaction was significant for ever asthma (p = 0.006), physician-diagnosed asthma (p = 0.01), and asthmatics showing bronchial hyperresponsiveness (p = 0.02), whereas interactions were not significant for persistent asthma (p = 0.12) or atopy (p = 0.46). Stratification by atopic status showed that interaction between NO₂ and NQO1 rs2917666 was more pronounced among non-atopic carriers of NQO1 rs2917666 C/C (OR = 2.38; 95% CI, 1.13–5.68; p-value for interaction = 0.01) compared with atopic subjects (OR = 1.24; 95% CI, 0.84–1.91; p-value for interaction = 0.45).

When stratified by sex [see Supplemental Material, Table 5 (doi:10.1289/ehp.0900589.S1)], interaction between NO₂ and rs2917666 was significant only among females (C/C: OR = 1.81; 95% CI, 1.13–3.09; p-value for interaction = 0.03) and not in males (C/C: OR = 1.39; 95% CI, 0.82–2.46; p-value for interaction = 0.24). However, heterogeneity by gender was not significant (p = 0.71). We observed no significant differences in the effect of NO₂ and NQO1 rs2917666 on current asthma by center (p-value for heterogeneity = 0.51). In addition, after including the random effects of center in a generalized mixed model, the interaction of NO₂ and NQO1 rs2917666 was still significant for the prevalence of asthma (p-value for interaction = 0.02). Heterogeneity was not significant among different socioeconomic strata based on occupation (p-value for heterogeneity = 0.28). The exclusion of nonrandomly selected symptomatic subjects in the second step of ECRHS II did not modify the effects observed in the whole sample (p-value for heterogeneity = 0.36).

**Discussion**

We evaluated the effect of genes involved in oxidative stress pathways (GSTM1, GSTT1, GSTP1, and NQO1), inflammatory response (TNFA), immunologic response (ILR4), and airway reactivity (ADRB2) on the association of traffic-related air pollution (using estimates of modeled NO₂ exposure) and adult asthma in a large, multicenter population-based cohort. We observed stronger associations between NO₂ concentrations and both prevalent and new-onset asthma among subjects homozygous for the most common allele of NQO1 compared with carriers of NQO1 variants. Although several studies have evaluated similar gene–environment interactions in children (Bergamaschi et al. 2001; David et al. 2003; Lee et al. 2004; Li et al. 2006; Melén et al. 2008; Romieu et al. 2004, 2006) and in experimental settings in adults (Corradi et al. 2002; Gilliland et al. 2004, 2006; Winterton et al. 2001; Yang et al. 2005), this is the first study examining the interaction of genetic variation and long-term air pollution on asthma in adults.

Similar to other studies, we used NO₂ level as a marker of traffic-related air pollution (Ekenius et al. 2003; Forastiere et al. 2006; Jacquemin et al. 2009; Melén et al. 2008; Modig et al. 2006; Morgenstern et al. 2008). Thus, the observed associations and interactions may be mediated by other ambient air pollutants, which are highly spatially correlated with NO₂. However, NO₂ is a strong oxidant per se, with a range of well-known adverse effects (Forastiere et al. 2006; Janssen-Heininger et al. 2002), and NO₂ either alone or combined with other pollutants may contribute to the observed effects (Forastiere et al. 2006).

In our study, we found a nonsignificant reduction of the NO₂ effects among carriers of at least one NQO1 Ser187 allele. The polymorphism that was associated with the most significant p-value in our study (rs2917666) is not known to be functional but is located in the 5’ upstream region of the gene. This region contains elements essential for the expression and induction of NQO1, such as the antioxidant response element that is required for NQO1 transcription in response to oxidative stress (Jaissal 2000; Nioi and Hayes 2004). The three SNPs in the NQO1 gene were in relatively weak linkage disequilibrium with the highest r² (0.53) found for the functional Pro187Ser (rs1800566) and rs2917666. Furthermore, the association between asthma and modeled NO₂ was significant for the most prevalent haplotype that contained the C allele of the rs2917666, which showed a significant interaction with NO₂ in the single SNP analysis. A few studies have evaluated the role of NQO1 in relation to exposure to O₃ [reviewed by Yang et al. (2008)] and have shown that the Pro187Ser (rs1800566) polymorphism was protective in response to O₃ when GSTM1 was present (Bergamaschi et al. 2001; Corradi et al. 2002; David et al. 2003). Susceptibility variants on oxidative stress genes GSTM1 and GSTP1 have been associated with an increased effect of air pollution and specific pollutants (Gilliland et al. 2004; Lee et al. 2004; Li et al. 2006; Melén et al. 2008; Romieu et al. 2004, 2006). In this study, we did not observe significant associations of GSTM1 or GSTP1 polymorphisms with asthma either alone or in combination with NQO1 SNPs. Lack of consistency with previous analyses could be related to the heterogeneity of effects in adults compared with children (Salam et al. 2008).

Our findings on NQO1 reinforce the role of antioxidant system in response to air pollution (Kelly 2003; Romieu et al. 2008). An in vitro approach proposed a hierarchical model to explain the dose-dependent

**Table 3. Association of NO₂ per 10-µg/m³ increase and asthma prevalence stratified by NQO1 and haplotypes in ECRHS II.**

| Haplotype | Allele | Prevalence | OR (95% CI) | p-Value | p-Value for interaction |
|-----------|--------|------------|-------------|---------|-------------------------|
| rs10517   | rs1800566 | rs2917666 |
| 1         | C      | C          | C           | 0.66    | 1.23 (1.03–1.48)        | 0.03 Reference |
| 2         | C      | T          | G           | 0.21    | 1.28 (0.90–1.89)        | 0.20 0.50       |

response to oxidant chemicals in DEP (Xiao et al. 2003) that will probably extend to gaseous pollutants like NO\textsubscript{2} (Saxon and Diaz-Sanchez 2005). With low exposure, the formation of ROS activates the transcription of genes involved in antioxidant responses, such as phase II enzymes (e.g., \textit{NQO1} and \textit{GST} genes). Higher exposure activates the transcription of nuclear factor-\textk{B} and activator protein-1, resulting in increased expression of proinflammatory cytokines (e.g., TNF-\textalpha), leading to additional generation of ROS (Romieu et al. 2008; Saxon and Diaz-Sanchez 2005).

The ECRHS is a large population-based international cohort that overcomes limitations of studies done in selected populations. The main limitations of this analysis include limited statistical power to detect interactions, some exposure misclassification, and heterogeneity and potential confounding concerning environmental exposures and genetic variation.

Statistical power to detect interactions was relatively low (Garcia-Closas et al. 1999). False-positive results have been shown to be frequent in studies on genetic variation and gene–environment interactions (Clayton and McKeigue 2001), and for these reason these results should be interpreted with caution. In this study we did not perform correction for multiple comparisons. However, traditional methods based on Bonferroni are overconservative because polymorphisms within a gene are not completely independent due to linkage disequilibrium. In addition, this correction may be acceptable when searching for significant associations without preestablished hypotheses, but we selected genes in this analysis on the basis of strong prior evidence.

Strengths and limitations of the NO\textsubscript{2} exposure assessment have been discussed previously (Jacquemyn et al. 2009). The individual assignment of exposure to NO\textsubscript{2} should result in a reduction of exposure misclassification. We evaluated NO\textsubscript{2} exposure by geoencoding home addresses of ECRHS participants and assigned ambient modeled NO\textsubscript{2} concentration derived from the APMoSPHERE map to each subject. The year of modeled NO\textsubscript{2} (2001) was concordant with the years of the administration of the ECRHS II questionnaire (1999–2002). However, the spatial scale of the APMoSPHERE model was relatively broad (1 x 1 km), and the model did not include monitors placed close to traffic. Thus, spatial and temporal contrasts in exposure due to very local emissions and dispersion patterns, such as those occurring in street canyons are unlikely to be captured. NO\textsubscript{2} does also capture part of that space but as a secondary gas is certainly more homogeneously distributed than, for example, ultrafine tail pipe particles. The misclassification is random in nature so, if anything, some bias toward the null may be expected. If those local peak concentrations were particularly relevant sources of exposure to oxidants, the APMoSPHERE-based results would likely underestimate true effects and interactions.

Because of the lack of repeated measurements during follow-up, exposure was assigned only to residences in ECRHS II. Although levels of air pollution did not remain constant during the follow-up period, the ranking in the spatial distribution of traffic-related pollutants is likely to remain similar. Exposure misclassification is thus particularly large among those who moved after ECRHS I, possibly explaining the smaller effects observed among movers (Beelen et al. 2008; Gotschi et al. 2008a).

Levels of air pollution and prevalence of asthma varied substantially across centers in ECRHS, showing a south–north gradient (Gotschi et al. 2008b; Jacquemyn et al. 2009; Suyner et al. 2009). Median levels of modeled NO\textsubscript{2} varied from 12 \textmu g/m\textsuperscript{3} in 2004 to more than 50 \textmu g/m\textsuperscript{3} in Umeå (Jacquemyn et al. 2009). Variables correlated with center, such as pollution composition, climatic factors, and diet, determine the individual response to air pollution (D’Amato et al. 2005). All results were adjusted by center, and random-effects meta-analysis suggested that NO\textsubscript{2} estimates and interactions with the genes were not center specific, although we acknowledge the limited power to detect this heterogeneity. In addition, recent analyses of population stratification among Europeans found correspondence between genetic variation and geographic distances, although levels of genetic diversity were low (Heath et al. 2008). Previous analyses in the ECRHS have shown little evidence of population stratification (Castro-Giner et al. 2008). However, this was based on an insufficient set of markers.

An important source of NO\textsubscript{2} exposure in the general population originates from the use of gas cookers (D’Amato et al. 2005). Several studies reported the association of indoor exposures with NO\textsubscript{2} outcomes and respiratory or allergic outcomes (Bernstein et al. 2008). In our data, outdoor NO\textsubscript{2} was not correlated with gas cooking, and adjustment for cooking with gas did not affect the observed effects of outdoor NO\textsubscript{2} and its interaction with the \textit{NQO1} polymorphism.

Differences were observed by sex, with females showing an increase in risk. However, the sample size of specific strata are smaller than the total population, and interpretation of these results should be done with caution. Our findings, if corroborated by others, may have significant public health implications because we identified a large group of susceptible subjects defined by the genetic makeup for whom the effect of modeled NO\textsubscript{2}-related air pollution on asthma was substantial. The affected subgroup was large, with a 46% prevalence of the C/C genotype for \textit{NQO1} rs2917666. Moreover, the number of people exposed to traffic-related pollution on a regular basis is large and as a consequence the burden of asthma related to ambient air pollution may be large not only in children, as previously documented, but also in adults.

Conclusions

Findings from this study suggest that genetic polymorphisms in the \textit{NQO1} gene are associated with susceptibility to asthma in adults among those exposed to traffic-related air pollution. This result points to the importance of antioxidant pathways in the effects of air pollution on asthma.
