**Highlights of the Study**

- Young adults (21–29 years) with children were more likely to report having had coronavirus disease 2019 (COVID-19) than young adults with no children.
- Among adults aged ≥30 years, having children was not associated with increased prevalence of COVID-19.
- Results of this report highlight the potential role of children in the transmission of COVID-19.

Coronavirus disease 2019 · Severe acute respiratory syndrome coronavirus 2 · Children

**Abstract**

**Objectives:** The role of children in the transmission of coronavirus disease 2019 (COVID-19) remains unclear. We investigated whether having children is associated with self-reported COVID-19 among adults. **Subjects and Methods:** A web-based cross-sectional study enrolled adults living in Kuwait (n = 2,355; aged ≥21 years). Prior COVID-19 diagnosis and having children were self-reported. Associations were assessed using Poisson regression, and adjusted prevalence ratios (aPRs) and 95% confidence intervals (CIs) were estimated. **Results:** Of the 2,355 participants (1,595 female subjects), 744 (31.6%) and 605 (25.7%) were of age 21–29 and 30–39 years, respectively. Overall, 4.8% (114/2,355) of the participants reported having had COVID-19, with 4.8% of females and 5.1% of males reporting prior COVID-19 diagnosis. In the total study sample, having children showed a trend for association with having had COVID-19 (aPR: 1.46, 95% CI: 0.99–2.14, \( p = 0.056 \)). Among participants aged 21–29 years, having children was associated with an increased prevalence of COVID-19 (aPR: 2.50, 95% CI: 1.21–5.20, \( p = 0.014 \)). Such an association was not detected in adults aged ≥30 years. **Conclusions:** Our epidemiological findings highlight the possible role of children in spreading COVID-19. Hence, preventive measures should consider the role of children.

**Introduction**

In the early stages of the coronavirus disease 2019 (COVID-19) pandemic, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), children were detected to be less susceptible to SARS-CoV-2 infection than adults, as COVID-19 disproportionately affects more adults than children [1]. However, this view has been modified as emerging investigations have shown that children are at a similar risk of infection as adults, but the clinical presentation of COVID-19 among children is different from that among adults, with the majority of children demonstrating mild or no symptoms [2].

Thus far, the role of children in spreading SARS-CoV-2 infection is unclear. A systematic review concluded that although limited studies have investigated the transmissibility of SARS-CoV-2 by children, some evidence of onward transmission from children exist [3]. Given the high viral load and prolonged viral shedding in pediatric COVID-19 patients and that most infected children may go unrecognized [2, 4], children can play a significant role in spreading the infection to their family and community. In this report, we used a population-based sample to investigate whether having children <18 years of age is associated with self-reported COVID-19 among adults and if this association differs according to the age of the adults. Such an epidemiological investigation may further our understanding of the role of children in SARS-CoV-2 transmission and guide public health policies.

**Subjects and Methods**

Adults were enrolled (n = 2,368; ≥21 years) in a cross-sectional study by completing an online questionnaire that was disseminated to residents of Kuwait between August 26 and September 1, 2020. The web-based questionnaire was disseminated using social media platforms, including Twitter, Instagram, and WhatsApp, as described in details by Alqudeimat et al. [5]. The snowball sampling technique, a nonprobability sampling method which yields a convenience sample, was used to recruit participants. The study was approved by the Health Sciences Center Ethics Committee for Student Research at Kuwait University (No. 754/2020). Completing the questionnaire was an indication of consent.

Participants reported demographic characteristics and self-reported if they have had received a COVID-19 diagnosis by a healthcare provider and whether their diagnosis was confirmed by real-time reverse transcription-polymerase chain reaction. Moreover, participants reported whether they have children, and those who reported having children further indicated whether any of their children are <18 years of age. In this analysis, subjects with no children and those with all of their children aged ≥18 years were grouped together. Hence, we analyzed a dichotomous variable: have children <18 years of age (yes/no). The current analysis included subjects with complete information for all study variables (n = 2,355).

Analyses were conducted using SAS 9.4 (SAS Institute, Cary, NC, USA). Frequencies and proportions of categorical variables were calculated in the total study sample and after stratification by self-reported COVID-19 diagnosis status, and differences in proportions were evaluated using χ² tests. Associations between having children <18 years of age (exposure) and self-reported COVID-19 diagnosis (outcome) were assessed in the total study sample and stratified by age-groups of the participants. Associations were adjusted for age, sex, nationality, educational attainment, and employment status. A modified Poisson regression with robust variance estimation was applied to estimate and infer adjusted prevalence ratios (aPRs) and 95% confidence intervals (CIs). Additional analysis assessed the associations between having children <18 years of age and self-reported COVID-19 diagnosis while stratifying by both age and sex of the participants.

**Results**

Of the 2,355 participants (1,595 female subjects), 114 (4.8%) self-reported having had COVID-19 and 1,113 (47.3%) reported having children <18 years of age (Table 1). Of the 114 adults who self-reported having had COVID-19, 104 (91.2%) reported that the diagnosis was confirmed by real-time reverse transcription-polymerase chain reaction. The prevalence of self-reported COVID-19 diagnosis did not differ according to the sex (males: 5.1% vs. females: 4.8%, p = 0.705) and age of the participants (Table 1). However, the prevalence of self-reported COVID-19 diagnosis was higher among non-Kuwaiti than among Kuwaiti subjects (7.8% vs. 4.6%, p = 0.034), employed compared to unemployed participants (6.0% vs. 2.9%, p < 0.001), and was highest among subjects who reported an educational attainment of high school or less and least among those with a bachelor’s degree (9.0% vs. 3.8%, p = 0.011; Table 1).

In the total study sample, participants with “children aged <18 years” were more likely to have had COVID-19 than those with “no children or with children aged ≥18 years” (5.5% vs. 4.3%; aPR: 1.46, 95% CI: 0.99–2.14; Table 2), though this association did not gain statistical significance. Among participants aged 21–29 years, “having children aged <18 years” compared to “having no children or all children aged ≥18 years” was associated with an increased likelihood of having had COVID-19 (12.0% vs. 4.1%; aPR: 2.50, 95% CI: 1.21–5.20). However, such an association was not evident in participants aged ≥30 years (Table 2). In additional analysis shown in Table 3, the association between having children aged <18 years and self-reported COVID-19 diagnosis was further stratified by sex.
and age (21–29 years vs. ≥30 years) of the participants. Among males aged 21–29 years (aPR: 2.10, 95% CI: 0.82–5.37) and aged ≥30 years (aPR: 3.92, 95% CI: 0.93–16.53), having children aged <18 years was associated with a trend of increased prevalence of self-reported COVID-19 diagnosis (Table 3). However, having children aged <18 years was associated with an increased prevalence of self-reported COVID-19 diagnosis only among females aged 21–29 years (aPR: 2.96, 95% CI: 1.08–8.74; Table 3).

### Discussion

The findings of this study showed that young adults with children are more likely to experience COVID-19 than young adults with no children. However, this association was not evident among older adults. Moreover, results of the analysis stratified by sex and age (Table 3) showed that young (aged 21–29 years) males and females with children aged <18 years were more likely than subjects with no children or with children aged ≥18 years to self-report COVID-19 diagnosis. Hence, indicating that the observed association between having children and experiencing COVID-19 among young adults was not modified by the sex of the participants. Such observations can be explained by the fact that young adults mainly have young children who are usually in close contact with parents and, hence, more likely to transmit infections to parents than older children. This hypothesis is supported by the fact that none of the participants aged 21–29 years reported having children aged ≥18 years. Nonetheless, we observed an elevated prevalence of self-reported COVID-19 diagnosis that is related to having children aged <18 years among males aged ≥30 years, but not among females aged ≥30 years. This observation of a sex-specific association among older adults warrants further corroboration. In general, our epidemiological observation suggests that children potentially play a role in spreading COVID-19.

Our findings contradict prior investigations that reported that pediatric COVID-19 patients account for a small proportion of familial transmission of the infection [6]. Nevertheless, these studies were based on symptom-

atic children, whereas the majority of children does only develop unrecognizable or no symptoms, and still can spread the infection [4]. Therefore, the prior studies are limited by only investigating the role of children who develop COVID-19 symptoms; hence, these results may underestimate the role of asymptomatic patients, which has been deemed to be important in the spread of COVID-19 [7]. In support of our findings, a study showed that children aged 0–14 years had the highest rate of transmitting SARS-CoV-2 infection to contacts as compared to other age-groups [8]. Another study concluded that children are as likely as adults to transmit SARS-CoV-2 in household setting [9]. Moreover, a large retrospective cohort study showed that among adults aged ≤65 years, living
with children was associated with an increased risk of recorded SARS-CoV-2 infection and COVID-19-related hospitalization [10]. These findings further support our observation of an association between having children and having had COVID-19. The higher viral load detected in young children compared to older children and adults further highlight the potential role of children in SARS-CoV-2 transmission [4, 11].

A limitation to our study is the lack of information on the number and exact age of children. Our findings should be considered as exploratory and corroborated by future studies. Given that most countries are opening up or planning to open schools, protocols are needed to reduce transmission while children are in school as they have the potential to spread the infection to their household and community.

Conclusion

Results of this report further our understanding of the role of children in the COVID-19 pandemic and highlight the need for preventive measures that aim to contain the potential spread caused by children.

Statement of Ethics

The study was approved by the Health Sciences Center Ethics Committee for Students Research at Kuwait University (No. 754/2020). Completing the questionnaire was an indication of consent to participate. The study was conducted in accordance with principles and guidelines of the Declaration of Helsinki for medical research involving human subjects.

Conflict of Interest Statement

The authors have no conflicts of interest to declare.

Funding Sources

No funding was received for this study.
