SUMMARY

The CsPbI₃ inorganic perovskite is a potential candidate for fabricating long-term operational photovoltaic devices owing to its intrinsic superb thermal stability. However, the carbon-based CsPbI₃ perovskite solar cells (C-PSCs) without hole transport material (HTM) are currently disadvantaged by their relatively low power conversion efficiency resulting from the poor grain quality and mismatched energy band levels of the as-made CsPbI₃ films. Herein we demonstrate that by doping Na into the CsPbI₃ lattice, the grain quality is significantly improved with low defect density, and also, the energy band levels are better matched to the contact electrodes, affording a higher built-in potential. Consequently, the Voc of the C-PSCs is drastically increased from 0.77 to 0.92 V, and the efficiency from 8.6% to 10.7%, a record value for the CsPbI₃ PSCs without HTM. Moreover, the non-encapsulated device showed virtually no performance degradation after 70 days of storage in air atmosphere.

INTRODUCTION

Organic-inorganic hybrid perovskite solar cells (PSCs) have attracted tremendous attention for their rapidly rising power conversion efficiency (PCE), currently reaching over 23%, achieved by solution-based techniques (Kojima et al., 2009; Lee et al., 2012; Mei et al., 2014; Yang et al., 2017). However, the organic ions in the organic-inorganic hybrid perovskites can easily escape from lattice under thermal stress, which restricts their long-term practical application (Wang et al., 2016; Park et al., 2016; Kim et al., 2016; Manser et al., 2016). In this regard, inorganic perovskites appear to be highly promising light absorbers owing to their good thermal stability (Duan et al., 2018; Yang et al., 2018). Among various inorganic perovskites, CsPbI₃ perovskite is the most suitable one because of its appropriate band gap (1.73 eV) for photovoltaic (PV) applications (Eperon et al., 2015; Frolova et al., 2016; Sanehira et al., 2017; Wang et al., 2018a, 2018b).

Other than the potential problems of perovskites as an active layer material in PSCs, the adoption of organic hole transport materials (HTMs) may also limit the stability of PSCs because they are commonly thermally unstable and susceptible to ion migration and metal electrode corrosion eventually causing device degradation (Swarnkar et al., 2016; Eperon et al., 2015; Luo et al., 2016; Liang et al., 2017b). To tackle this issue, proposal has been put forward to replace the organic HTM and the metal electrode with a carbon electrode, which for the past few years has proved to be an effective approach (Chen and Yang, 2017). Some works on carbon-based HTM-free PSCs (C-PSCs) have employed CsPbI₃ as a light absorber, and in our own work, a PCE of 9.5% has been achieved previously (Xiang et al., 2018). However, such a PCE is far lower than those achieved by the C-PSCs based on organic-inorganic hybrid perovskites. According to the previous works, the low PCE can be mainly attributable to the low obtainable open-circuit voltage (Voc) (Ball et al., 2013; Han et al., 2015; Zhang et al., 2017; Liang et al., 2017a), i.e., below 0.8 V. The low Voc should originate from the low grain quality of CsPbI₃ film or the mismatched energy band levels at charge collection interface (Ahmad et al., 2017; Eperon et al., 2015; Zhang et al., 2018; Chen et al., 2018; Sanehira et al., 2017).

Herein, we address the above issues by doping the CsPbI₃ inorganic perovskite at A site with Na element. It is found that the Na doping not only improved the morphology of CsPbI₃ film but also significantly enhanced the grain quality, thus reducing the defect density. Furthermore, the Na doping offers a good handle to adjust the energy band levels of CsPbI₃ film, raising the built-in potential and Voc. As a result, C-PSCs based on the Na-doped CsPbI₃ film achieved a PCE as high as 10.7% with a Voc of 0.92 V, which are considerably higher than those obtained by the C-PSCs based on pure CsPbI₃ film (PCE = 8.6%,

https://doi.org/10.1016/j.isci.2019.04.025
Voc = 0.77 V). Besides, the non-encapsulated C-PSCs based on the Na-doped CsPbI3 film exhibit almost no PCE degradation after 70 days of storage in a dry air atmosphere.

The whole procedure of C-PSC fabrication, including CsPbI3 deposition, was conducted in a dry air atmosphere (humidity ~10%–20%). The CsPbI3 films were deposited on TiO2 mesoporous scaffolds via a one-step spin-coating method with the precursor solution containing ~1 M N,N-Dimethylformamide (DMF)–HI–PbI2, (1-x) M CsI, and x M NaI, followed by heating at 200°C to obtain black CsPbI3 perovskite films.

X-ray diffraction (XRD) patterns of the perovskite films with different Na doping concentrations are shown in Figure 1A. As depicted in Figures 1A and 1B, with Na doping content increasing, the (100) peak shifts to a higher 2θ, correlating to the lattice contraction. Therefore Na ions should have partially replaced Cs ions in the CsPbI3 lattice because Na atoms (1.02 Å) are significantly smaller than Cs atoms (1.67 Å). Moreover, as depicted in Figure S1, the films after storage for 7 days show almost the same XRD patterns as the corresponding as-prepared films, suggesting high phase stability. Secondary ion mass spectroscopy was further employed to study the composition difference between CsPbI3 and Cs0.95Na0.05PbI3 films. The depth profiling in Figures 1C and S2 shows that Na ions have been doped into the CsPbI3 film, which distribute throughout the whole film. As a side note, Na atom concentration in the capping layer is slightly lower than that in the mesoporous layer. This could be interpreted as follows. The tolerance factor of CsPbI3 perovskite is small (t = 0.81), and it would be further lowered after the substitution of Cs with Na atoms, which would reduce the structural stability. To make the structure stable, Na atoms might thermodynamically tend to stay in the mesoporous TiO2 scaffold, because the nanopores in the scaffold could confine grain dimensions to nanosize (Choi et al., 2013) and there may be lattice strain at the CsPbI3/TiO2 interface, which both would help to stabilize the perovskite structure. Similar phenomenon has been reported for organic-inorganic perovskites when the ions with a large size mismatch degree were used as dopants (Qiao et al., 2018). To identify the chemical states of CsPbI3 and Cs0.95Na0.05PbI3 films, X-ray photoelectron spectra (XPS) have also been recorded. The high-resolution XPS spectra for various elements (Na 1s, Cs 3d, Pb 4f and I 3d) are shown in Figures 1D and S3. Notably, a uniform shift in the peak positions of Cs 3d and Pb 4f to a lower binding energy is observed for Cs0.95Na0.05PbI3 film, whereas the peak position of I 3d shifts to a higher binding energy. These shifts should be correlated to the Na doping because the smaller
Na atoms would cause the volume contraction of the BX₆ (B = Pb or Mn; X = I or Br) octahedral and hence lead to the changes in chemical bonding (Zou et al., 2017; Li et al., 2016).

To evaluate PV performance, paintable C-PSCs (as illustrated in Figure 2A) were fabricated by directly painting a commercial carbon paste on the CsPbI₃ and Cs₀.₉₅Na₀.₀₅PbI₃ films, followed by annealing at 120°C for 30 min (Chen et al., 2015, 2016). The cross-sectional scanning electron microscopic (SEM) image of the C-PSCs in Figure 2A indicates an intimate contact at the CsPbI₃/carbon interface.

The average PV parameters obtained from the CsPbI₃ and Cs₁₋ₓNaₓPbI₃ (0 ≤ x ≤ 0.1) cells are shown in Figures 2B–2E. The average open-circuit voltage ($V_{oc}$) increases progressively with Na incorporation, from 0.78 ± 0.02 V for x = 0 to 0.88 ± 0.02 V for x = 0.05, and then slightly declines to 0.86 ± 0.01 V for x = 0.10. With Na doping concentration increasing, the short-circuit current density ($J_{sc}$) decreases gradually, from 17.0 ± 0.53 mA/cm² for x = 0 to 15.9 ± 0.1 mA/cm² for x = 0.10. Similar with $V_{oc}$, the fill factor (FF) also gradually increases as x increases from 0 to 0.05, and then reduces as x further increases to 0.10, with 5% Na (FF = 0.68 ± 0.02) outstanding among the others. As a result, the PCE increases from 7.9% ± 0.3% for the pristine CsPbI₃ device to 10.0% ± 0.4% for the Cs₀.₉₅Na₀.₀₅PbI₃ one. Interestingly, even for the perovskites containing 10% Na, the PV performance is still superior to the pure CsPbI₃, with an average PCE of 9.19% ± 0.3%.

The current density versus voltage (J-V) curves of the champion CsPbI₃ and Cs₀.₉₅Na₀.₀₅PbI₃ C-PSCs devices are presented in Figure 3A. The champion CsPbI₃ C-PSCs obtain a $V_{oc}$ of 0.77 V, $J_{sc}$ of 17.76 mA/cm², and FF of 0.627, which leads to a PCE of 8.6%, whereas the champion Cs₀.₉₅Na₀.₀₅PbI₃ device shows a $V_{oc}$ of 0.92 V, $J_{sc}$ of 16.5 mA/cm², and FF of 0.703, which generates a PCE of 10.7%, a new record PCE for HTM-free
CsPbI3 PSCs (Liang et al., 2017a; Xiang et al., 2018). It can be clearly seen that the large increase in PCE mainly benefits from the obvious improved Voc and FF, which would be further discussed below.

Figure 3B displays the plots of the PCEs that are obtained at the voltage close to the maximum power output point as a function of time, indicating that under constant illumination the steady-state PCEs of the CsPbI3 and Cs0.95Na0.05PbI3 C-PSCs are about 10.23% and 8.18%, respectively. In Figure S4, the J–V curves obtained from different scan directions show that both C-PSCs show similar hysteresis. The incident photon-to-electron conversion efficiency (IPCE) spectra (Figure 3C) are further taken for illustrating the Jsc decrease of the doped devices. Compared with Cs0.95Na0.05PbI3 C-PSCs, CsPbI3 C-PSCs show higher IPCE values in the whole wavelength, generating the integrated Jsc of 17.0 mA/cm² versus 15.55 mA/cm², which is well consistent with the Jsc extracted from the J–V curves. The cross-sectional SEM images in Figure S6A indicate that the film thickness of the two perovskite layers are almost the same (230 nm). Thus the lower absorption coefficient should be responsible for the decreased Jsc of Na-doped C-PSCs, as proved with the ultraviolet-visible (UV-vis) spectra in Figures 4C and S9.

The long-term stability of CsPbI3 and Cs0.95Na0.05PbI3 C-PSCs was also tested (Figure 3D) with the non-encapsulated devices stored in dry air atmosphere (20°C–35°C and 10%–20% humidity). Promisingly, both C-PSCs show excellent stability and almost no PCE degradation is detected after storage for more than 70 days. The photostability measurement of the devices under continuous one-sun illumination (100 mW/cm²) was also conducted in ambient atmosphere (20°C and 40% humidity). As shown in Figure S5, Cs0.95Na0.05PbI3 device demonstrates a higher photostability than the CsPbI3 one and 80% of the initial PCE has been retained after degradation for 24 h.

To get insights into the performance difference between the two C-PSCs, more characterizations on the perovskite films and C-PSCs were conducted. Top-view SEM images of CsPbI3 and Cs0.95Na0.05PbI3 films in Figures 4A and 4B show that after Na doping, the film surface becomes slightly smoother and the grain size becomes slightly larger, with the average size increasing from ~243 nm to around 288 nm (as shown in Figure S7). As further confirmed by atomic force microscopic images in Figure S6B, the roughness value (Ra) decreases from 19.9 to 18.3 nm after Na doping. However, such small improvement in film morphology could not well account for the PV performance difference.
Absorption coefficient versus wavelength curves of TiO2/CsPbI3 and TiO2/Cs0.95Na0.05PbI3 thin films have been further measured. As shown in Figure 4C, the absorption coefficient decreases after Na doping, which well explains the decreased Jsc of the Na-doped devices. Steady-state photoluminescence (PL) and time-resolved PL (TRPL) spectra were further employed to evaluate the grain quality of CsPbI3 and Cs0.95Na0.05PbI3 films. As shown in Figure S8, the steady-state PL peaks of the two films appear at a very close wavelength, which is consistent with the UV-vis spectra in Figure S9. As shown in Figures S9C and S9D, the band gaps of CsPbI3 and Cs0.95Na0.05PbI3 are measured to be 1.67 and 1.68 eV, respectively. As clearly seen, the PL intensity of the Cs0.95Na0.05PbI3 film is significantly higher than that of the CsPbI3 film, suggesting a higher grain quality with less defects (Vorpahl et al., 2015; Tan et al., 2017; Pan et al., 2018). TRPL spectra of the bare perovskite films on glass substrate in Figure 4D show an obviously slower quenching rate after Na doping. After fitting, the average PL lifetime is calculated to be about 40 ns for the Cs0.95Na0.05PbI3 film, almost two times longer than that of the CsPbI3 film, well confirming the lower defect density induced by Na doping for suppressing charge recombination. To more vividly depict PL lifetime difference, the PL lifetimes throughout the perovskite films were also mapped. As shown in Figures 4E and 4F, the PL lifetime of the CsPbI3 film is mainly around 10–15 ns, as highlighted by the light green color, whereas most of the area on the Cs0.95Na0.05PbI3 film shows a PL lifetime of over 20 ns, as depicted by orange color. Therefore steady-state PL, TRPL, and PL lifetime mapping all confirm a higher grain quality with lower defect density after Na doping.

Absorption coefficient versus wavelength curves of TiO2/CsPbI3 and TiO2/Cs0.95Na0.05PbI3 thin films have been further measured. As shown in Figure 4C, the absorption coefficient decreases after Na doping, which well explains the decreased Jsc of the Na-doped devices. Steady-state photoluminescence (PL) and time-resolved PL (TRPL) spectra were further employed to evaluate the grain quality of CsPbI3 and Cs0.95Na0.05PbI3 films. As shown in Figure S8, the steady-state PL peaks of the two films appear at a very close wavelength, which is consistent with the UV-vis spectra in Figure S9. As shown in Figures S9C and S9D, the band gaps of CsPbI3 and Cs0.95Na0.05PbI3 are measured to be 1.67 and 1.68 eV, respectively. As clearly seen, the PL intensity of the Cs0.95Na0.05PbI3 film is significantly higher than that of the CsPbI3 film, suggesting a higher grain quality with less defects (Vorpahl et al., 2015; Tan et al., 2017; Pan et al., 2018). TRPL spectra of the bare perovskite films on glass substrate in Figure 4D show an obviously slower quenching rate after Na doping. After fitting, the average PL lifetime is calculated to be about 40 ns for the Cs0.95Na0.05PbI3 film, almost two times longer than that of the CsPbI3 film, well confirming the lower defect density induced by Na doping for suppressing charge recombination. To more vividly depict PL lifetime difference, the PL lifetimes throughout the perovskite films were also mapped. As shown in Figures 4E and 4F, the PL lifetime of the CsPbI3 film is mainly around 10–15 ns, as highlighted by the light green color, whereas most of the area on the Cs0.95Na0.05PbI3 film shows a PL lifetime of over 20 ns, as depicted by orange color. Therefore steady-state PL, TRPL, and PL lifetime mapping all confirm a higher grain quality with lower defect density after Na doping.

Mott-Schottky analyses of CsPbI3 and Cs0.95Na0.05PbI3 C-PSCs were carried out to get built-in potential (Vbi), which is related to the Voc of C-PSCs (Laban and Etgar, 2013; Almora et al., 2016). As shown in Figure 5A, the Vbi can be obtained by using the intercept of the linear regime with the x axis of the...
The $V_{bi}$ for the CsPbI$_3$ and Cs$_{0.95}$Na$_{0.05}$PbI$_3$ C-PSCs are about 0.74 V and 0.90 V, respectively. Such difference in $V_{bi}$ is in good agreement with the Voc values obtained from the J-V curves in Figure 2B. The larger $V_{bi}$ would assist in more efficient charge separation and collection, which is favorable for achieving higher Voc and FF (Wang et al., 2018b). Therefore the increase in $V_{bi}$ should be an important cause for the performance improvement.

As well known, the difference in $V_{bi}$ is usually reflected from the change in energy band levels (Wang et al., 2015). The energy band levels of CsPbI$_3$ and Cs$_{0.95}$Na$_{0.05}$PbI$_3$ films were characterized by the combination of UV photoelectron spectroscopy (Figures 5B and 5C) and UV-vis spectra (Figure S9). The final energy band levels of CsPbI$_3$ and Cs$_{0.95}$Na$_{0.05}$PbI$_3$ are depicted in Figure 5D. It can be indicated that both perovskite films are n-type semiconductors. Compared with CsPbI$_3$ film, all energy band levels of Cs$_{0.95}$Na$_{0.05}$PbI$_3$ film are obviously lifted, especially for $E_f$. The higher ECBM may be favorable for electron injection from Cs$_{0.95}$Na$_{0.05}$PbI$_3$ to TiO$_2$. The lifting of the $E_f$ would induce a larger upward band bending at the Cs$_{0.95}$Na$_{0.05}$PbI$_3$/carbon interface as depicted in Figures 5E and 5F, which would promote hole transfer. The obtained $V_{bi}$ from the Mott-Schottky analysis may predominantly form at perovskite/carbon interface because the potential drop at the n-n junction of TiO$_2$/perovskite interface should be negligible (Jiang et al., 2015; Guerrero et al., 2014).

According to intensity-modulated photocurrent/phovoltage spectroscopy results, the relationship of light intensity ($I_0$) with electron diffusion coefficients ($D_n$) and electron lifetime ($\tau_n$) could be obtained, as shown in Figure S10. Based on the equation $L_n=(D_n\tau_n)^{1/2}$, diffusion length ($L_n$) could be calculated (Zhu et al., 2007; Zhao and Zhu, 2013). As depicted in Figure S10C, the $L_n$ of Cs$_{0.95}$Na$_{0.05}$PbI$_3$ C-PSCs is obviously larger than that of CsPbI$_3$ C-PSCs, which further confirms the lower charge recombination loss and more efficient charge collection.

In conclusion, we have significantly increased the Voc and PCE of CsPbI$_3$ C-PSCs by doping Na into the CsPbI$_3$ lattice. The resulting morphology shows a slight difference between CsPbI$_3$ and Cs$_{0.95}$Na$_{0.05}$PbI$_3$ films, but the grain quality was significantly improved with a lower defect density for the doped sample.
Spectroscopic measurements showed that all energy band levels (EVBM, E\text{CBM}, and E\text{F}) were lifted up after Na doping, which afforded a better match to the contact electrode and hence supported a larger V\text{oc} for obtaining a higher V\text{oc} (0.92 V) for C-PSCs. As a result, the Cs_{0.95}Na_{0.05}PbI\text{3} C-PSCs achieved a PCE as high as 10.7\text{%}, which is a new record value for the \text{\alpha}-Cs\text{PbI}_{3} PSCs without HTM. More promisingly, the non-encapsulated Cs_{0.95}Na_{0.05}PbI\text{3} C-PSCs exhibited almost no performance degradation after 70-day storage in a dry air atmosphere. Therefore Na doping is an effective way to fabricate CsPbI\text{3} C-PSCs with high performance and high stability.

Limitations of the Study
Organic-inorganic hybrid PSCs have attracted great interest because of their rapidly rising PCE. However, the volatility of the organic cations in these materials restricts long-term practical application. The CsPbI\text{3} inorganic perovskite with intrinsic superb thermal stability is a potential candidate to fabricate prolonged stable operational PV devices. However, the efficiency of carbon-based PSCs (C-PSCs) without HTM, the most promising commercial PSCs, is relatively low due to the poor crystalline quality and mismatched energy band levels of CsPbI\text{3}. Herein, by doping Na into the CsPbI\text{3} lattice, the PCE of C-PSCs is largely improved especially the open circuit potential. The important achievements are as follows:

(1) The Na doping not only improves the morphology of CsPbI\text{3} film but also significantly enhances crystalline quality to reduced defect density.

(2) All energy band levels of CsPbI\text{3} are lifted up to match contact electrodes after Na doping, which helps to support a much higher built-in potential for obtaining an increased V\text{oc} from 0.77 to 0.92 V.

(3) Na-doped C-PSCs achieve an efficiency of 10.7\text{%}, a new record value of the CsPbI\text{3} PSCs without HTM.

(4) The non-encapsulated Na-doped C-PSCs exhibit almost no performance degradation after 70 days of storage in air atmosphere.

METHODS

**Transparent Methods**

**Preparation of TiO\textsubscript{2} mesoporous scaffolds.** Firstly, TiO\textsubscript{2} blocking layer was spin-coated on cleaned FTO glass at 2000 rpm for 20 s using 0.15 M titanium diisopropoxide bis(acetylacetonate) in 1-butanol solution, followed by heating at 125 °C for 5 min. Then, TiO\textsubscript{2} films was deposited by spin coating at 5000 rpm for 30 s using a commercial TiO\textsubscript{2} paste (Dyesol 30 NRD, Dyesol) diluted in ethanol with a ratio of 1:2.5. After drying at 100 °C for 5 min, the TiO\textsubscript{2} films were gradually heated to 550 °C, baked at this temperature for 30 min and cooled to room temperature.

**Deposition of CsPbI\textsubscript{3} and Cs\textsubscript{1-x}Na\textsubscript{x}PbI\textsubscript{3} films.** DMF·HI·PbI\textsubscript{2} powder was prepared as introduced in our previous work\textsuperscript{[6]}, mixing 5 g PbI\textsubscript{2} and 4 ml HI in DMF and stirring overnight to ensure complete conversion. Light yellow DMF·HI·PbI\textsubscript{2} precipitates were obtained by pouring abundant ethanol into the above solution, followed by washing the precursor in ethanol for several times. The precipitates was filtered and dried in a vacuum oven at 60 °C for 2 h. CsPbI\textsubscript{3} films were deposited by one-step deposition method. The CsPbI\textsubscript{3} precursor solution was prepared by dissolving 1 M DMF·HI·PbI\textsubscript{2} and 1M CsI in DMF solvent at room temperature. The solution was spin-coated on the substrates that had been preheated to 70 °C at 2000 rpm for 20 s. Then, the samples were annealed at 200 °C for around 5 min to get CsPbI\textsubscript{3} films. For the Cs\textsubscript{1-x}Na\textsubscript{x}PbI\textsubscript{3} films, the whole procedure was similar except replacing xM CsI with NaI in the precursor solution.

**Deposition of carbon electrode.** A commercial carbon paste purchased from Guangzhou Seaside Technology Co., Ltd was used as carbon paint for carbon electrode. The carbon extraction layer was simply deposited by printing the carbon paint on CsPbI\textsubscript{3} films at room temperature, followed by heating at 120 °C for 30 min.

**Films characterizations.** X-ray diffraction (XRD) patterns were recorded on a Philips PW-1830 X-ray diffractometer with Cu K\textsubscript{α} radiation (K = 0.15418 nm). TOF-SIM was used to detect distribution of different elements, collected in the positive ion detection mode employing 30 keV Bi\textsuperscript{+} primary beam with a diameter of 100 um and recorded on TOF.SIMS 5-100. The beam was at an angle of 45° with respect to the sample surface normal. Morphology was evaluated on a JEOL 6700F or 7100F SEM at an accelerating voltage of 5 kV. UV-vis absorption spectra were recorded on a Perkin-Elmer UV-vis spectrophotometer (model Lambda 20). Steady state PL spectra were measured on a Jobin Yvon (Laboratory RAM HR800) confocal micro-Raman spectrometer. Time resolved PL measurement was carried out on an ultrafast lifetime Spectrofluorometer (Delta flex) and a 475 nm ultrafast laser was used as the excitation light source. Fluorescence lifetime image were recorded on a laser scanning confocal microscope (A1R-si). Chemical states of film surface were evaluated by an X-ray photoemission spectroscopy (XPS, ESCALab250Xi). The energy positions were recorded on an ultraviolet photoelectron spectroscopy (UPS, ESCALab250Xi).

**Photovoltaic characterizations.** The solar light simulator (Newport Oriel Sol3A, model number 94063A, AM 1.5 global filter) was calibrated to 1 sun (100 mW/cm\textsuperscript{2}) using an Oriel reference solar cell (monocrystalline silicon) and meter. The active cell area was all fixed at about 6.25 mm\textsuperscript{2} using a metal mask. Each ten cells were used to collect the relevant cell parameters of different doping amount in Figure 2(b)-(e). J–V curves and intensity modulated photocurrent/photovoltage spectroscopy (IMPS/IMVS) and open-circuit voltage decay (OCVD) measurement were recorded.
on a ZENNIUM pro electrochemical workstation (ZAHNER-Elektrik GmbH & Co., KG, Germany). The wavelength of the irradiation light for IMPVS and OCVD measurement is 417 nm. IPCE spectra were recorded using IPCE kit (E0201, Institute of Physics, Chinese Academy of Sciences) in AC mode.

**Stability evaluation.** The device stability was studied by storing the device under room temperature (20-30 °C) in air atmosphere with a humidity lower than 30 %. J-V curves were measured periodically in ambient air (about 30-80 % humidity) to get the photovoltaic parameters. The photostability was tested under continuous one-sun illumination (100 mW/cm$^2$) at RT and 65 °C in ambient atmosphere without encapsulation (humidity~40%).
