Supporting Information

ABSTRACT: Metal–organic frameworks (MOFs) are usually synthesized using a single type of metal ion, and MOFs containing mixtures of different metal ions are of great interest and represent a methodology to enhance and tune materials properties. We report the synthesis of [Ga₂(OH)₂(L)] (H₄L = biphenyl-3,3′,5,5′-tetracarboxylic acid), designated as MFM-300(Ga₂), (MFM = Manchester Framework Material replacing NOTT designation), by solvothermal reaction of Ga(NO₃)₃ and H₂L in a mixture of DMF, THF, and water containing HCl for 3 days. MFM-300(Ga₂) crystallizes in the tetragonal space group I4,22, a = b = 15.0174(7) Å and c = 11.9111(11) Å and is isostructural with the Al(III) analogue MFM-300(Al₂) with pores decorated with −OH groups bridging Ga(III) centers. The isostructural Fe-doped material [Ga₁₋ₓFeₓ(OH)₁₋ₓ(L)] (MFM-300(Ga₁₋ₓFeₓ)), can be prepared under similar conditions to MFM-300(Ga₂) via reaction of a homogeneous mixture of Fe(NO₃)₃ and Ga(NO₃)₃ with biphenyl-3,3′,5,5′-tetracarboxylic acid. An Fe(III)-based material [Fe₀.₁₃Gₐ₀.₈₇(OH)(HL)(L)] (H₂O)₁₃(MFM-310(Fe)), was synthesized with Fe(NO₃)₃ and the same ligand via hydrothermal methods. [MFM-310(Fe)] crystallizes in the orthorhombic space group Pnnm, with a = 10.560(4) Å, b = 19.451(8) Å, and c = 11.773(5) Å and incorporates μ₁-oxo-centered trinuclear iron cluster nodes connected by ligands to give a 3D nanoporous framework that has a different structure to the MFM-300 series. Thus, Fe-doping can be used to monitor the effects of the heteroatom center within a parent Ga(III) framework without the requirement of synthesizing the isostructural Fe(III) analogue [Fe₀.₁₃(OH)(L)] (MFM-300(Fe₀.₁₃)), which we have thus far been unable to prepare. Fe-doping of MFM-300(Ga₂) affords positive effects on gas adsorption capacities, particularly for CO₂ adsorption, whereby MFM-300(Ga₁₋ₓFeₓ) shows a 49% enhancement of CO₂ adsorption capacity in comparison to the homometallic parent material. We thus report herein the highest CO₂ uptake (2.86 mmol g⁻¹ at 273 K at 1 bar) for a Ga-based MOF. The single-crystal X-ray structures of MFM-300(Ga₃-solv), MFM-300(Ga₂), MFM-300(Ga₁₋ₓFeₓ-solv), MFM-300(Ga₁₋ₓFeₓ), and MFM-300(Ga₁₋ₓFeₓ·2.35CO₂) have been determined. Most notably, in situ single-crystal diffraction studies of gas-loaded materials have revealed that Fe-doping has a significant impact on the molecular details for CO₂ binding in the pore, with the bridging M−OH hydroxyl groups being preferred binding sites for CO₂, within these framework materials. In situ synchrotron IR spectroscopic measurements on CO₂ binding with respect to the −OH groups in the pore are consistent with the above structural analyses. In addition, we found that, compared to MFM-300(Ga₂), Fe-doped MFM-300(Ga₁₋ₓFeₓ) shows improved catalytic properties for the ring-opening reaction of styrene oxide, but similar activity for the room-temperature acetylation of benzaldehyde by methanol. The role of Fe-doping in these systems is discussed as a mechanism for enhancing porosity and the structural integrity of the parent material.
INTRODUCTION

Porous metal–organic frameworks (MOFs) have attracted a great deal of interest because of their potential applications in gas adsorption and separation, catalysis, and drug delivery.1–3 The assembly of MOF materials from various metal ions and organic linkers, usually via solvothermal reactions, allows the fine-tuning of their crystal structures and the incorporation of designed functional groups for specific applications. Indeed, the properties, size, and functionality of the cavity of these porous materials can be optimized by using different metal centers or organic ligands.4–6 Amine (−NH₂) groups can bind selectively to CO₂ due to the formation of strong electrostatic interactions between the electronegative N center of the −NH₂ group and the electropositive C center of the CO₂ molecule.4 For this reason, a number of amine-functionalized MOFs have been designed and synthesized to capture CO₂ from flue gases.7,8 However, the effect of the different metal ions in MOFs on CO₂ adsorption properties has been rarely studied. While frameworks based on divalent transition metal centers have been extensively explored and are now well-developed,9 MOFs with trivalent metal centers have generally attracted less attention.10 Furthermore, few examples of gallium-carboxylate MOFs are described in the literature.11 MOFs are usually constructed from a single type of metal cation and organic linker, but there are increasing examples of MOFs which contain two different types of ligand linkers or metal cations with a homogeneous distribution, as found in solid solutions.12–23 Kitagawa et al.17 and Cheetham et al.18 et al. have reported the syntheses and properties of some binary and ternary MOF solid solutions which contain a mixture of similar organic linkers. In addition, Serre et al. have reported mixed-metal MIL-53(FeCr), which exhibits a new type of framework topology as Fe-MOF-74.21 [Fe(NO₃)₂(C₂O₄)·2H₂O] converts ethane into EtOH and acetaldehyde with 37% HCl (2 drops) were reacted in a pressure tube at 384 K for 3 days. The yellow crystalline product was separated by filtration, washed several times with warm water, and dried in air. Yield: 85%. Elemental analysis (% calc/found) for [Ga(NO₃)₃(H₂O)]·H₂O·1DMF (C₁₇H₁₆NO₆Ga): C, 34.43/34.21; H, 3.80/3.14; N, 2.11/1.70. Rapid loss of free solvent molecules and hydration during the sample transfer are responsible for the discrepancy and the variability observed in the elemental analytical data for this material. Selected IR (cm⁻¹): 3648(m), 3432(s), 2928(w), 1650(m), 1603(w), 1455(w), 1376(m), 1318(m), 1126(m), 875(w). Synthesis of MFM-300(FeNO₃). Fe(NO₃)₃·9H₂O (290 mg, 0.72 mmol), and piperazine (0.10 g, 1.26 mmol) were mixed and dispersed in water (10.0 mL) containing nitric acid (2.0 mL, 2.7 M) in a Teflon autoclave and heated at 483 K for 3 days. The yellow crystalline product was separated by filtration, washed several times with water, and dried in air. Yield: 10%. These hydrothermal conditions afforded two phases which were light yellow and dark purple in color. Single-crystal X-ray diffraction identified the yellow light phase as MFM-300(Fe), while the other phase (Fe(NO₃)₃) was isolated only as a fine powder. Since we have found no method as yet for their separation as pure phases, no further characterization has been undertaken.

Synthesis of MFM-300(Ga(NO₃)₃·9H₂O·1DMF). A mixture of Fe(NO₃)₃·9H₂O (3.16 mg, 0.0072 mmol), Ga(NO₃)₃ (38 mg, 0.1486 mmol), and H₂O (22.0 mg, 0.0676 mmol) in a 2:5:1 mixture of DMF, THF, and water (8 mL) slightly acidified with 37% HCl (2 drops) was reacted in a pressure tube at 384 K for 3 days. The yellow crystalline precipitate was separated by filtration, washed several times with warm water, and dried in air. Yield: 85%. Elemental analysis (% calc/found) for [Ga(NO₃)₃(H₂O)]·H₂O·1DMF (C₁₇H₁₆NO₆Ga): C, 34.43/34.21; H, 3.80/3.14; N, 2.11/1.70. Rapid loss of free solvent molecules and hydration during the sample transfer are responsible for the discrepancy and the variability observed in the elemental analytical data for this material. Selected IR (cm⁻¹): 3648(m), 3432(s), 2928(w), 1650(m), 1603(w), 1455(w), 1376(m), 1318(m), 1126(m), 875(w). Synthesis of MFM-300(FeNO₃). Fe(NO₃)₃·9H₂O (290 mg, 0.72 mmol), and piperazine (0.10 g, 1.26 mmol) were mixed and dispersed in water (10.0 mL) containing nitric acid (2.0 mL, 2.7 M) in a Teflon autoclave and heated at 483 K for 3 days. The yellow crystalline product was separated by filtration, washed several times with water, and dried in air. Yield: 10%. These hydrothermal conditions afforded two phases which were light yellow and dark purple in color. Single-crystal X-ray diffraction identified the yellow light phase as MFM-300(Fe), while the other phase (Fe(NO₃)₃) was isolated only as a fine powder. Since we have found no method as yet for their separation as pure phases, no further characterization has been undertaken.

confirmed a significant enhancement (49%) of CO₂ adsorption upon controlled Fe-doping. Single-crystal X-ray diffraction studies on both solvated and desolvated materials confirm the structural integrity of these materials, and notably, in situ single-crystal diffraction studies under a CO₂ atmosphere have been used to determine the preferred binding sites of CO₂ within these MOFs and to explain the changes in the molecular guest binding mechanism upon Fe-doping. In situ synchrotron IR spectroscopy has also been used to study the details of CO₂ binding with respect to the −OH groups in the pore. Furthermore, catalytic experiments have also confirmed that MFM-300(Ga(NO₃)₃·9H₂O·1DMF) shows higher conversion rates than MFM-300(Ga(NO₃)₃) for the ring-opening reaction of styrene oxide.

MATERIALS AND METHODS

Chemicals. Gallium nitrate (Ga(NO₃)₃, 99%, Aldrich), iron nitrate (Fe(NO₃)₃·9H₂O, 99%, Sigma), hydrochloric acid (HCl, >99%, Fisher Scientific), nitric acid (HNO₃, >99%, Fisher Scientific), piperazine (99%, Sigma-Aldrich), DMF (>99%, Fisher Scientific), and THF (99.9%, Fisher Scientific) were used as purchased. Biphosph-3,3',5,5'-tetracarboxylic acid (H₄L) (Scheme 1) was synthesized by a literature method.24

Scheme 1. View of Biphosph-3,3',5,5'-tetracarboxylic Acid (H₄L)
Growth of MOF Crystals on SiO$_2$ Surfaces. Silicon (100) wafers with a 300 nm SiO$_2$ thin oxide layer were cut mechanically and then washed in methanol, acetone, and isopropanol for 10 min each. The wafers were dried under a stream of N$_2$ and placed into the above reaction solutions, which were then heated in a pressure tube. Single crystals of MOF products grew on these surfaces over 3 days under the same solvothermal conditions. We found this methodology to be highly effective in growing good quality single crystals for subsequent structural characterization.

SEM, EDX, and ICP Measurements. MOF crystals grown on SiO$_2$ substrates were coated with carbon using an Agar turbo carbon coater to improve conductivity. Scanning electron microscope (SEM) analysis was performed on a FEI Quanta 3D 200 dual beam focused ion beam scanning electron microscope (FIB-SEM). The images were acquired using secondary electron imaging at an accelerating voltage of 5 kV. An Oxford Instruments integrated INCA Energy 250 Microanalysis System was used for EDX elemental spectra and mapping, and ICP-OES measurements were made on a PerkinElmer Optima 2000.

Growth of Single Crystals of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv. Single crystals of MFM-300(Ga)$_2$-solv were obtained under solvothermal conditions as detailed above, and we also attempted to grow crystals of both MFM-300(Ga)$_2$-solv and MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv on a SiO$_2$ surface. Immersion of the prepared SiO$_2$ substrate into a reaction solution of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv leads to the formation of uniform cubic single crystals of 30–50 μm in length. The growth of MOF crystallites on surfaces has been observed previously but has been used rarely for the growth of single crystals. We were unable to grow single crystals of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv in the absence of the SiO$_2$ substrate (Figure 1).

Figure 1. SEM images for (a, b) MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv and (c, d) MFM-300(Ga$_2$)-solv grown on SiO$_2$ surfaces.

Structure Determination and Refinement for MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv (x = 0, 0.13). High-resolution powder diffraction data for the as-synthesized MOFs were collected on Beaml ine 111 at Diamond Light Source using multi-analyzing-crystal (MAC) detectors. The powder pattern was first indexed on a body-centered tetragonal lattice, and the independent unit cell parameters were refined using TOPAS. The body centring and the reflection condition 00l, l = 4n indicates that the space group is one of the enantiomeric pair I4$_1$/22 and I4$_1$/22. In the absence of any component capable of directing chirality, the product is expected to be a 1:1 racemic mixture. The structure solution was initially established in space group I4$_1$/22 starting from the structural model of MFM-300(Ga$_2$) and further developed by subsequent difference Fourier analysis using TOPAS. The final structure refinement was carried out using the Rietveld method with isotropic displacement parameters for all atoms. The highly disordered DMF molecules in the pores could not be located and modeled and, therefore, were treated as discrete water molecules in the refinement. A total of 40 disordered water molecules per unit cell were found within the channels and included in the final structure refinement for MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv (x = 0, 0.13). The final stage of the Rietveld refinement involved soft restraints to the C–C bond lengths within the benzene rings.

Structure Determination and Refinement for MFM-300(Ga$_2$)-solv, MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv, MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-2.35CO$_2$, MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-2.0CO$_2$, MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-2.6DMF, and MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-2.35CO$_2$·2.0CO$_2$. Single-crystal diffraction data of MFM-300(Ga$_2$) and MFM-300(Ga$_{1.87}$Fe$_{0.13}$) were collected on Beamline I19 at Diamond Light Source within a gas cell system. A single crystal of MFM-300(Ga$_2$)-solv or MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv was loaded into the gas cell, which was then flushed with dry N$_2$. The diffraction data were collected at room temperature. The gas cell was then evacuated at 10$^{-4}$ mbar and heated at 393 K using an Oxford Cryosystems open-flow nitrogen cryostat for 4 h to generate the desolvated material MFM-300(Ga$_2$) or MFM-300(Ga$_{1.87}$Fe$_{0.13}$). Diffraction data were collected under vacuum after cooling to room temperature. The gas cell was then cooled to 195 K and exposed to dry CO$_2$ for 2 h. The diffraction data were then collected at 195 K under 1.0 bar pressure of CO$_2$. The structures were solved by direct methods and developed by difference Fourier techniques using the SHELXTL software package. A total of 6.4 DMF and 16 water molecules, and 10.8 water molecules per unit cell were found within the pores, and these were included in the refinement of MFM-300(Ga$_2$)-1.6DMF·4H$_2$O and MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-2.7H$_2$O, respectively. Importantly, no residual electron density was apparent within the pores of desolvated MFM-300(Ga$_2$) and desolvated MFM-300(Ga$_{1.87}$Fe$_{0.13}$), confirming the complete removal of guest solvent molecules. A total of 9.4 and 8.0 CO$_2$ molecules per unit cell were found to occupy two independent sites within the pore and these were included in the refinement of MFM-300(Ga$_2$)-2.35CO$_2$ and MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-2.0CO$_2$ respectively. The hydrogen atoms on the ligands and DMF molecules were placed geometrically and refined using a riding model. The hydrogen atoms of free water molecules could not be located but are included in the molecular formula and in values derived from it. CCDC 951538–951543 and 1009553 contain the supplementary crystallographic data for this paper.

In Situ Infrared Spectroscopy. IR spectroscopic measurements were carried out on the B22 MIRIAM beamline at the Diamond Light Source using a Hyperion 3000 infrared microscope with a 15× objective and a liquid N$_2$ cooled MCT detector. The sample was mounted in a Linkam FTIR600 variable-temperature gas-tight stage fitted with ZnSe windows, and ZnSe-based linear IR polarizers were used to obtain polarized IR spectra. Spectra were collected (256 scans) in the range 650–4000 cm$^{-1}$ with 4 cm$^{-1}$ resolution and an infrared spot size at the sample of approximately 25 by 25 μm. The sample was activated in the stage prior to measurements by heating at 150 °C under a slow flow of N$_2$ for 10 h before being transferred to the microscope and purged under He flow at room temperature. CO$_2$ and He were delivered to the Linkam stage using separate mass-flow controllers, the partial pressure of CO$_2$ being controlled by varying the volumetric flow of the two gases. Both gases were predried through zeolite filters placed between the cylinders and the mass-flow controllers before being flowed through the Linkam stage.

Gas Sorption. Sorption isotherms for CO$_2$, CH$_4$, N$_2$, and H$_2$ were recorded at 77 K (liquid N$_2$), 87 K (liquid Ar), and 273–303 K (temperature-programmed bath from Hiden Company) on an IGA-003 system under ultrahigh vacuum from a diaphragm and turbo pumping system. All gases used were ultrapure research grade (99.999%) purchased from BOC or AIRLIQUIDE. The density of the desolvated samples used in the study were 1.80 g cm$^{-3}$ estimated from the crystallographic density of the desolvated sample by PLATON/SOLV. In a typical gas adsorption experiment, ca. 50 mg of as-synthesized material was loaded into the IGA and degassed at 100 °C and high vacuum (10$^{-10}$ bar) for 1 day to give fully desolvated samples.
Scheme 1, H to be 50%. The approximate evolution of products was monitored by GC, and the products were analyzed by GC–MS by using a Hewlett-Packard 5890 series gas chromatograph with an FID detector and high-purity helium as the carrier gas. The products were determined by using a Hewlett-Packard 5890 series gas chromatograph with an FID detector and high-purity helium as the carrier gas. The products were identified by comparison with an authentic sample.

In a typical experiment, the activated MOF catalyst (20 mg) was suspended in MeOH (5 mL), followed by the addition of benzaldehyde. The reaction was performed at the required temperature, the evolution of products was monitored by GC–MS by using a Hewlett-Packard 6890 series spectrometer. The regioselectivity of 1a was determined by mass spectrometry, which shows different fragmentation patterns depending on the relative position of the nucleophilic group. In the case of 2-methoxy-2-phenylethanol, the structure was confirmed by comparison with an authentic sample.

In a typical experiment, the activated MOF catalyst (20 mg) was suspended in MeOH (5 mL), followed by the addition of 1a or benzaldehyde. The reaction was performed at the required temperature, the evolution of products was monitored by GC, and the products were analyzed by GC–MS. After the required time, the catalyst was removed by filtration, washed with MeOH, and dried at 80 °C. This dried catalyst was activated again and used for the second run with fresh 1a and methanol.

RESULTS AND DISCUSSION

Synthesis and Structural Description. Biphenyl-3,3′,5,5′-tetracarboxylic acid (Scheme 1), H$_2$L, was reacted with Ga(NO$_3$)$_3$ in a 2:5:1 mixture of DMF, THF, and water (8 mL) slightly acidified with HCl in a pressure tube at 348 K for 3 days to give MFM-300(Ga$_2$)-solv. MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv was prepared in a similar manner but using an intimate mixture of Fe(NO$_3$)$_3$·9H$_2$O and Ga(NO$_3$)$_3$ as the metal source. The structures of MFM-300(Ga$_2$)-solv and MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv were solved by single-crystal and high-resolution synchrotron powder diffraction data, respectively. Indexation of powder diffraction patterns (PXRD) of these complexes confirms that they are isomorphous to MFM-300(Al$_2$)-solv.

MFM-300(Ga$_2$)-solv crystallizes in the chiral tetragonal space group I4,22 and shows an open three-dimensional framework structure constructed from one-dimensional helical [Ga(OH)$_2$O]$_{\infty}$ chains bridged by tetracarboxylate ligands (Figure 2). The Ga(III) ion is octahedrally coordinated by six O-donors: four from carboxylate groups [Ga–O = 2.004(3) and 1.999(4) Å] and two from mutually cis bridging hydroxyl groups $\mu_2$OH [Ga–O = 1.928(3) Å]. This coordination also affords a square-shaped, one-dimensional channel running through the framework parallel to the c-axis. In the analogous complex MFM-300(Al$_2$)-solv, the four bonds from the carboxylates are slightly shorter [Al–O = 1.935(1) and 1.929(2) Å] than those in MFM-300(Ga$_2$)-solv, but the two bonds from the $\mu_2$-OH groups are very similar [Al–O = 1.930(1) Å]. The approximate diameter of the channel in MFM-300(Al$_2$)-solv, taking into account the van der Waals radii of surface atoms, is 6.7 × 6.7 Å. The channel contains uncoordinated water (2.0 per Ga) and DMF (0.8 per Ga) molecules, giving a formula of [Ga$_2$(OH)$_2$-(C$_{12}$H$_{20}$O$_6$)(DMF)$_{1.6}$(H$_2$O)$_4$ for the as-synthesized material. The DMF molecule interacts with the hydroxyl group to form a moderate hydrogen bond [O–O = 2.694(6) Å; O–H···O = 180°], and two disordered water molecules form weak intermolecular hydrogen bonds [O–O = 2.94(3) Å]. The hydrogen atoms on the water molecules were not located. The total pore voids occupied by the free solvents were estimated by PLATON/SOLV to be 50%.

The solvated framework complex MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv was prepared via solvothermal reaction of H$_2$L and Ga(NO$_3$)$_3$/Fe(NO$_3$)$_3$·9H$_2$O in DMF/THF/water containing HCl. Whereas these conditions yielded cube-shaped single crystals of MFM-300(Ga$_2$)-solv with an average size of 20–50 μm, the solvothermal synthesis of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv yielded microcrystalline solids with an approximate particle size of 5 μm rather than crystals large enough for single-crystal structure determination. Rietveld refinement confirms the phase purity of the bulk material.

![Figure 2](https://example.com/figure2.png)

**Figure 2.** Views of the crystal structure of MFM-300(Ga$_2$). (a) View of the [Ga(OH)$_2$O]$_{\infty}$ chain; (b) projection of the structure along the a-axis; (c) view of the channel running through the framework parallel to the c-axis. (Ga: green; O: red; H: white; ligand L$^-$ is represented by gray lines.)
and confirms that the Fe-doped material MFM-300(Ga$_{1.87}$Fe$_{0.13}$) has the same framework structure as MFM-300(Ga$_2$), with very small differences in unit cell parameters (Table S1). This is consistent with the similar ionic radii of Ga(III) and Fe(III) and the low level of doping. A similar modulation in unit cell parameters has been observed in the Fe$^{2+}$-exchanged material Mn$_3$[(Mn$_4$Cl)$_3$- (BTT)$_3$]$_2$ (BTT$^{3-} = 1,3,5$-benzenetristetrazolate) following postsynthetic cation methathesis. 31 Subsequently, single crystals of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv were successfully grown on SiO$_2$ substrates as described above, and their single-crystal structure determination is entirely consistent with the structure derived from PXRD.

Attempts to form the isostructural MFM-300(Fe$_2$)-solv have thus far failed. A nonisostructural complex was synthesized under different hydrothermal conditions using only an Fe(III) metal source to give the trinuclear Fe$_3$-cluster-based material [Fe$_3$O$_{1.5}$ (OH) (HL) (H$_2$O)$_{3.5}$] $\mu_3$-oxo centered trinuclear iron clusters connected by L$^{4-}$ ligands generate a three-dimensional nonporous framework (Figure 3). This trinuclear iron cluster is connected through an oxygen positioned at the center of an isosceles triangle of 3.57(3) Å (Figure 3a). Interestingly, this trinuclear iron cluster incorporates different carboxylate connectivity compared to the more usual Fe$_3$O(CO$_2$)$_6$-type cluster reported previously in the literature. 32, 33 PXRD data for MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv confirm the absence of the MFM-310(Fe) phase, suggesting that a solid solution has been formed, rather than a mechanical binary mixture of MFM-300(Ga$_2$)-solv, MFM-300(Fe$_2$)-solv and MFM-310(Fe). Furthermore, no splitting or broadening of PXRD peaks attributable to the presence of a binary mixture of phases was observed, even when using a synchrotron radiation source ($\Delta \theta < 0.005^\circ$), supporting the formation of a fully mixed doped material (Figure S1).

The synthesis of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv emanated from a preparation using metal salt starting materials in an Fe:Ga molar ratio of 5:95. Characterization of the Fe content by ICP for successive isolated samples from the above synthetic procedure consistently gave metal content ratios of MFM-300(Ga$_{1.87}$Fe$_{0.13}$)-solv ($\chi = 0.13$) (equivalent to 6.5% doping). SEM/EDX confirmed the even spread of Fe throughout the sample.

We also targeted materials MFM-300(Ga$_{2-x}$Fe$_x$)-solv with higher Fe doping levels of 10, 15 and 20%. With increasing Fe content, the PXRD patterns of the isolated powders indicated the presence of more amorphous materials, and more critically, we found that the reproducibility of these higher Fe-doped materials was very poor, with significant variations in Fe content from batch to batch. Thus, only MFM-300(Ga$_2$) doped with Fe at the 5% level in the synthesis (giving 6.5% in the product) is presented here. The partial replacement of one metal cation by another is most likely to be successful in the case of a series of isostructural compounds. 23 In this case, however, the

(FeO$_6$ octahedron: green; Fe: yellow; O: red; C: gray/black).](image-url)
isostructural MFM-300(Fe) cannot be isolated using the synthetic conditions reported here.

**Gas Adsorption Properties.** MFM-300(Ga$_{1-x}$Fe$_x$)-solv ($x = 0, 0.13$) are thermally stable up to 573 K before decomposition, as confirmed by TGA (Figure S7). The desolvated materials were prepared by soaking the as-synthesized sample in acetone for 5 days, followed by degassing under dynamic vacuum $(10^{-10}$ bar) at 100 °C for 20 h, to obtain the fully desolvated samples. The CO$_2$ isotherms at 273 K show type-I behavior with reversible uptake (Figure 4). The pore size distributions (PSDs) for both MFM-300(Ga) and MFM-300(Ga$_{1.87}$Fe$_{0.13}$) show one broad peak at approximately at 5.5 Å, close to the approximate diameter of the channel window $(6.7$ Å). The surface areas from the CO$_2$ isotherms were calculated to be 392 and 491 m$^2$ g$^{-1}$ for MFM-300(Ga) and MFM-300(Ga$_{1.87}$Fe$_{0.13}$), respectively. The values for BET surface area and pore size obtained from the N$_2$ isotherms are in good agreement with those calculated from CO$_2$ (Table 1). These surface areas are considerably lower than that of the isostructural MFM-300(Al)$_2$ (1370 m$^2$ g$^{-1}$), taking into account the increased formula weight by ~21% on going from Al to Ga. A similar difference in BET surface area between Al- and Ga-containing isostructural materials has been also observed in [Al(BTB)] and [Ga(BTB)] (BTB$^-$ = benzenetribenzoate), where the surface areas are reported as 1045 and 62 m$^2$ g$^{-1}$, respectively. The BET surface areas for MFM-300(Ga) are reproducible over many batches of material. This discrepancy could be due to a number of factors: not all the void space within a porous material is necessarily accessible by the gaseous substrate in the BET and gas adsorption experiments, while the bulk powder sample may not correspond precisely to the idealized structure determined by single-crystal diffraction due to partial collapse of the framework and/or blocking of pores by phase changes and different domains within the material. Notwithstanding the full structural analysis of these materials, it remains possible that residual free solvent molecules or reactant molecules remain in the pores, leading to blocking effects limiting gas entry and uptake. The phase purity of the as-synthesized bulk samples has been confirmed by high-resolution synchrotron X-ray powder diffraction data, which do not show the presence of bulk impurities (Figure S4). The total micropore volume for MFM-300(Ga) was estimated from CO$_2$ isotherms to be 0.201 cc g$^{-1}$ increasing to 0.299 cc g$^{-1}$ upon Fe-doping (Table 1). Thus, such doping has a positive effect on the micropore volume, increasing it by 49%; we ascribe this effect to increased structural integrity of the Fe-doped material giving a more ordered, and thus more porous, material with more accessible pores.

Gravimetric CO$_2$ sorption isotherms were also measured at 195 K (1 bar) and 303 K (up to 20 bar) for desolvated MFM-300(Ga$_{1-x}$Fe$_x$) ($x = 0, 0.13$) to evaluate the effect of mixing metal cations on CO$_2$ uptake capacity. At 195 K and 1 bar, MFM-300(Ga) shows a maximum uptake of 4.72 mmol g$^{-1}$, whereas MFM-300(Ga$_{1.87}$Fe$_{0.13}$) shows a maximum uptake of 7.02 mmol g$^{-1}$, corresponding to a 49% increase in CO$_2$ adsorption (Figure 3). This result further suggests that MFM-300(Ga$_{1.87}$Fe$_{0.13}$) is a homogeneous, single-phase material: if it were simply a mechanical binary mixture of two pure M(III) (M = Ga, Fe), in order to achieve 7.02 mmol g$^{-1}$ CO$_2$ uptake for the mixture, MFM-300(Fe) would need to have a CO$_2$ uptake of 35.17 mol g$^{-1}$, which is 3 times higher than the maximum uptake calculated based on the single-crystal structure.

At 273 K and up to 1 bar, MFM-300(Ga$_{1-x}$Fe$_x$) ($x = 0, 0.13$) show a maximum CO$_2$ uptake of 2.87 and 3.51 mmol g$^{-1}$ for $x = 0$ and $x = 0.13$, respectively. Compared with MFM-300(Ga), the CO$_2$ uptake in the Fe-doped MOF thus shows an increase of 22%. This value is consistent with those observed at 195 K and 1 bar, confirming the enhancement of CO$_2$ adsorption in the doped material. Interestingly, although Fe-doping has a positive effect on CO$_2$ uptake capacities, the heat of CO$_2$ adsorption counterintuitively decreases upon Fe-doping [34.7 and 30.9 kJ mol$^{-1}$ for MFM-300(Ga) and MFM-300(Ga$_{1.87}$Fe$_{0.13}$)].
A slight decrease in surface area (\(m^2\) pore voids (%)) for MFM-300(Ga\(_{1-x}\)Fe\(_x\)) (\(x = 0, 0.13\)) is due to the presence of more open and available pores within MFM-300(Ga\(_{1-x}\)Fe\(_{0.13}\)) rather than any specific enhanced chemical effects of doping with Fe.

MFM-300(Ga\(_{1-x}\)Fe\(_{0.13}\)) adsorbs more H\(_2\) at 77 K and 20 bar (1.61 wt %) than MFM-300(Ga\(_x\)) (1.45 wt %). In addition, both materials display substantially higher H\(_2\) uptake capacities compared to MFM-300(Al\(_x\)) (<0.2 wt %), even though the latter has the higher internal surface area. A slight decrease in the heat of adsorption (\(Q_a\)) is observed for MFM-300(Ga\(_{1-x}\)Fe\(_{0.13}\)) (9.7 kJ mol\(^{-1}\)) in comparison to MFM-300(Ga\(_x\)) (10.3 kJ mol\(^{-1}\)), indicating slightly weaker H\(_2\)-framework interactions as a result of Fe-doping (Figure S10). The high heat of adsorption for H\(_2\) uptake in MFM-300(Ga\(_{1-x}\)Fe\(_x\)) (\(x = 0, 0.13\)) is due to strong overlapping potential between the adsorbed H\(_2\) molecules and the narrow pore size (5.5 Å) of these materials.

**Table 1. Summary of Gas Adsorption Data for MFM-300(Ga\(_{1-x}\)Fe\(_x\)) (\(x = 0, 0.13\))**

| X     | MFM-300(M) | BET surface area (m\(^2\)/g) | CO\(_2\) uptake at 195 K (mmol/g) | Heat of adsorption at low surface coverage | Heat of adsorption at 1 bar (mmol/g) | Heat of adsorption at 273 K (mmol/g) |
|-------|------------|------------------------------|-----------------------------------|-------------------------------------------|--------------------------------------|--------------------------------------|
| Al\(_x\) | 0.257      | 3.10                         | 3.10                              | 1.0                                      | 2.0                                  | 3.0                                  |

| Calcd. from CO\(_2\) data at 195 K. | 0.257      | 3.10                         | 3.10                              | 1.0                                      | 2.0                                  | 3.0                                  |

The fundamental antisymmetric CO\(_2\) stretching vibration is active in the region 1800–2400 cm\(^{-1}\). The IR spectra of MFM-300(Ga\(_x\)) crystals show in the absence of CO\(_2\) the \(\nu\)(OH) stretch at 3660 cm\(^{-1}\), which shifts \(\sim\)7 cm\(^{-1}\) to lower energy to 3653 cm\(^{-1}\) on increasing the partial pressure of CO\(_2\) from 0 to 1 bar (Figure S5). The difference spectra (Figure S17) clearly show a loss of the original band and the formation of a new, lower energy band, consistent with the formation of a hydrogen bond between –OH and adsorbed CO\(_2\) molecules in the narrow pores.

![Figure S5](https://example.com/figure_s5.png)

**Figure S5.** In situ FTIR spectra of a single crystal of MFM-300(Ga\(_x\)) in the \(\nu\)(OH) and CO\(_2\) combination band region on increasing the partial pressure of CO\(_2\) from 0 to 1 bar. The contribution from gaseous CO\(_2\) has been subtracted with reference to the blank cell as a function of CO\(_2\) loading.
MFM-300(Ga₂). Unsurprisingly, the combination bands of gaseous CO₂ increase in intensity as the CO₂ pressure increases and, on subtracting these bands from the spectra, two new lower-energy bands are revealed at 3696 and 3592 cm⁻¹. These new bands grow concurrently with the change in the −OH absorption and are consistent with the formation of an adsorbed CO₂ species in MFM-300(Ga₂). We have also examined the adsorbed CO₂ concentration in MFM-300(Ga₂) and the changes in the −OH vibration by fitting the peaks in this region to Lorentzian line shapes. The plot of peak area vs partial pressure of CO₂ (Figure S18), normalized such that the final absorption of each peak is set to 1, is entirely consistent with the isotherms obtained by gas sorption experiments and confirms that the formation of the lower energy ν(OH) band is concurrent with the rise in the adsorbed CO₂ combination bands. A new absorption band was also observed at 2275 cm⁻¹ (data not shown here), which we attribute as the fundamental vibration of adsorbed CO₂, but the rest of that region (2280–2400 cm⁻¹) is obscured by the absorbance for free CO₂ gas.

To probe further the Ga−OH···O=O=C=O interaction within the framework, we studied a single crystal of MFM-300(Ga₂) with well-defined faces using polarized IR spectroscopy. IR spectra measured using a synchrotron radiation source, which gives approximately 100 times higher photon flux density over typical laboratory sources, have much improved signal-to-noise ratios. This allows the accurate measurement of IR spectra with a polarized beam to study the orientation of the vibration modes with respect to the functional groups. The microscope was used to locate a single crystal that appeared to be lying flat on the stage window, and spectra were recorded of the sample after activation (under He) and under 1 bar of CO₂. Two orthogonal directions of polarized light were employed, both parallel to a crystal edge (Figure 6a), and the spectra are shown in Figure 6a. In the absence of CO₂, the IR spectrum recorded with polarization along the a̅b plane of the crystal (P1 as shown in Figure 6c) shows a single intense ν(OH) stretch at 3660 cm⁻¹, as observed in the unpolarized spectra. The spectrum recorded with polarization P2 (oriented 90° to P1, along c-axis) is markedly different, with an almost complete absence of the ν(OH) absorption. In the crystal structure, all the −OH groups in the framework are found pointing into the channels (in the a̅b plane), with no component along the c-axis (along the channels). Therefore, the polarized IR results are consistent with the polarization in P1 being aligned with the a̅b plane containing the −OH groups and P2 being aligned along the c-axis of the structure, orthogonal to the −OH groups and hence hardly interacting with the −OH dipole. Having identified the directionality of the crystal, the same orientations were investigated by loading the sample with 1 bar of CO₂ (Figure 6b). With polarization P1, the −OH vibration is still intense and, as with the unpolarized spectra, is shifted to lower energy (accompanied by a degree of peak broadening), indicative of a hydrogen bonding interaction with adsorbed CO₂. The CO₂ combination bands are again both present at 3696 and 3591 cm⁻¹; the higher energy CO₂ band is a combination of the ν₁ and ν₃ symmetric and antisymmetric vibrations, both of which are oriented along the O=O=C=O bond axis, leading to the potential assignment of the 3696 cm⁻¹ band in the P1 polarized IR spectrum to the presence of a CO₂ molecule hydrogen-bonded in an "end-on" fashion to and aligned along the same axis as the −OH groups. This combination band has a lower relative absorbance as a fraction of the ν(OH) band when compared with the unpolarized spectra peaks \[ A_{3696}^\text{P1} / A_{\text{OH}}^\text{P1} = 0.14:1 \] with polarization P1 vs...
interactions with adsorbed CO\textsubscript{2} adjacent to the \textendash OH group. Most notably, the CO\textsubscript{2} combination bands increase in absorbance by a factor of \~1.6 compared with the same bands observed at P1, commensurate with the presence of CO\textsubscript{2} molecules in an orientation much better aligned with the P2 polarization than P1. This suggests the presence of a second (or more) binding site within the framework and that, at 1 bar, the CO\textsubscript{2} molecules at the second site have higher occupancy than the end-on CO\textsubscript{2} molecules hydrogen-bonded to the \textendash OH groups. We thus sought to investigate this further by gaining more insight into the adsorption sites within the porous host by crystallographic methods.

**In Situ Single-Crystal Diffraction Studies.** To determine the preferred binding sites for adsorbed CO\textsubscript{2} molecules in MFM-300(Ga\textsubscript{2}), and MFM-300(Ga\textsubscript{1.87}Fe\textsubscript{0.13}), single crystals of as-synthesized MFM-300(Ga\textsubscript{2})-solv and MFM-300-(Ga\textsubscript{1.87}Fe\textsubscript{0.13})-solv were studied using an in situ gas cell system on a synchrotron radiation source. Upon degassing at 393 K under high vacuum (10\textsuperscript{-4} mbar), the desolvated materials MFM-300(Ga\textsubscript{2}) and MFM-300(Ga\textsubscript{1.87}Fe\textsubscript{0.13}) show cell volume contractions $\Delta V/V$ of 2.1% and 0.65%, respectively. The relatively small contraction for MFM-300(Ga\textsubscript{1.87}Fe\textsubscript{0.13}) is due to the synthesized crystals prepared on a SiO\textsubscript{2} surface substrate being partially dried during the sample transfer before the experiment. No electron density was found in the pore for these desolvated samples, confirming the effectiveness of the activation procedure and the retention of the framework structure which incorporates uncoordinated \textendash OH groups within the pore (Figures 7 and 8). The activated crystals were then exposed to 1 bar of CO\textsubscript{2} at 195 K, and the diffraction data were collected for the resulting CO\textsubscript{2}-loaded crystal. Significant residual electron density was now found in the pore by difference Fourier map analysis and was sequentially assigned as two independent CO\textsubscript{2} molecules populating at sites I (O\textsubscript{1}≡C\textsubscript{1}≡O\textsubscript{2}) and II (O\textsubscript{3}≡C\textsubscript{3}≡O\textsubscript{4}).

In MFM-300(Ga\textsubscript{2}), the occupancies for these CO\textsubscript{2} molecules at sites I and II refined to values of 0.43(3) and 0.74(3), respectively, yielding the overall formula $\left[\text{Ga}_2\left(\text{OH}\right)\left(\text{C}_6\text{H}_4\text{O}_3\right)\right] 
\cdot \text{2.35CO}_2$ for the CO\textsubscript{2}-loaded material. This result is in excellent agreement with the results of the adsorption studies.

**Figure 7.** Views of single-crystal structures of (a, d) MFM-300(Ga\textsubscript{2})-solv; (b, e) MFM-300(Ga\textsubscript{2}) activated at 393 K and vacuum 10\textsuperscript{-4} mbar for 4 h; (c, f) MFM-300(Ga\textsubscript{2})-2.35CO\textsubscript{2}, loaded with CO\textsubscript{2} at 1 bar at 195 K for 2 h. The guest molecules (DMF, water, CO\textsubscript{2}) in the channels are highlighted using a ball-and-stick style (Ga: green; C: gray; O: red; H: white; N: blue). The carbon atom of CO\textsubscript{2} molecules are highlighted in cyan (O···C\textsubscript{4}) and green (O···C\textsubscript{2h}).

**Figure 8.** Views of single-crystal structures of (a, d) MFM-300(Ga\textsubscript{1.87}Fe\textsubscript{0.13})-solv; (b, e) MFM-300(Ga\textsubscript{1.87}Fe\textsubscript{0.13}), activated at 393 K and vacuum 10\textsuperscript{-4} mbar for 4 h; (c, f) MFM-300(Ga\textsubscript{1.87}Fe\textsubscript{0.13})-2.0CO\textsubscript{2}, loaded with CO\textsubscript{2} at 1 bar at 195 K for 2 h. The guest molecules (DMF, water, CO\textsubscript{2}) in the channels are highlighted as ball-and-stick models (Ga: green; C: gray; O: red; H: white; N: blue). The carbon atom of CO\textsubscript{2} is highlighted in orange. The hydrogen bonding interaction between the guest molecule and free \textendash OH group is highlighted in purple. The electrostatic dipole interactions between CO\textsubscript{2} molecules are highlighted in cyan (O\textsubscript{1}···C\textsubscript{1}) and green (O\textsubscript{2}···C\textsubscript{2h}).
agreement with the experimental uptake from the CO₂ isotherm at 195 K (1.18 CO₂ per Ga). The CO₂ at site I is ordered and binds to the −OH group in an end-on fashion via a moderate hydrogen bonding interaction \([\text{H} \cdots \text{O}_1 = 1.883(10) \text{ Å}; \angle \text{O} - \text{H} \cdots \text{O}_1 = 180°]\), entirely consistent with the interaction observed by the IR spectroscopy. Interestingly, this hydrogen bond distance is much shorter than that observed in the MFM-300(Al)–3.2CO₂ system \([\text{H} \cdots \text{O} = 2.376(13) \text{ Å}; \angle \text{O} - \text{H} \cdots \text{O} = 180°]\) studied by in situ PXRD at 273 K, indicating the formation of a stronger hydrogen bonding interaction in MFM-300(Ga)–2.3CO₂. Given that MFM-300(Ga) and MFM-300(Al) have the same framework structure and pore surface chemistry, this difference in hydrogen bond length is most likely due to the different metal center (Al or Ga) affecting the relative acidity of the M−OH \((M = \text{Al}, \text{Ga})\) group. In addition to this hydrogen bond, O₁ also forms weak supramolecular contacts with aromatic hydrogen atoms from the phenyl rings \([\text{O}_1, \cdots \text{H} = 2.98(4), 3.14(3) \text{ Å}, \text{each occurring twice}\]. The CO₂ at site II is disordered over two equally occupied positions. In contrast to CO₂⁺, CO₂⁻ does not interact directly with framework atoms, instead forming two weak electrostatic dipole interactions with CO₂⁻, between the electropositive C and electronegative O centers \([\text{C}_2 \cdots \text{O}_2 = 3.85(4) \text{ Å}; \text{C}_2 \cdots \text{O}_2 = 4.39(4) \text{ Å}\). Significantly, this pattern of intermolecular interactions is distinct from the traditional “T-shaped” dipole interaction observed in solid CO₂ in \([\text{Zn}_2(\text{atz})_2(\text{ox})\cdot 1.3\text{CO}_2] \quad \text{at} \quad \text{at} = \text{3-amino-1,2,4-triazolate; } \text{ox}^2− = \text{oxalate}^− \text{and in MFM-300(Al)}_2\text{-3.2CO}_2^− \text{and is, for the first time, determined here. Furthermore, both the position and the relative occupancy of these sites are in excellent agreement with the experimentally observed polarized IR absorbances for adsorbed CO₂ aligned with and perpendicular to the −OH axis at room temperature. CO₂ molecules at site I are aligned with the direction of P₁, and CO₂ molecules at site II, while not perfectly orthogonal to site I, have a significantly better alignment with P₂ than P₁. The increase in IR absorbance of the higher energy CO₂ combination band \((\text{factor of } 1.6) \text{ in P₂ compared with P₁ is remarkably close to the crystallographically observed ratio of site occupancies (II: I = 1:7:1), both experiments having been carried out at 1 bar CO₂ pressure.}

In contrast, the occupancy of the CO₂ molecules at sites I and II in MFM-300(Ga₁₈₋₅Fe₁₃₋₁₃) both refined to values of 0.50 (1), yielding a formula of \([\text{Ga}_{1₅₋₇}\text{Fe}_{₁₃₋₁₃}(\text{OH})_2\text{C}_₆\text{H}_₄\text{O}_₂] \cdot 2\text{CO}_₂\) for the CO₂-loaded material. However, this result is lower than the experimental uptake from the CO₂ isotherm at 195 K, which implies the formation of MFM-300(Ga₁₈₋₅Fe₁₃₋₁₃)-2.9CO₂. The discrepancy could be due to two factors: (i) the kinetic effect for the population of CO₂ molecules within the whole single crystal; (ii) some of the faces of the single crystals could have been blocked or damaged when it was removed from the surface substrate, thereby reducing the diffusion rate for CO₂ molecules. Nevertheless, this discrepancy does not prevent us from determining the binding mechanisms. The CO₂ at site I is ordered and binds to the −OH group in an end-on fashion via a weak hydrogen bonding interaction \([\text{H} \cdots \text{O}_1 = 2.259(12) \text{ Å}; \angle \text{O} - \text{H} \cdots \text{O}_1 = 180°]\). Interestingly, this hydrogen bond distance is longer than that observed in the MFM-300(Ga)–2.35CO₂ system \([\text{H} \cdots \text{O}_1 = 1.883(10) \text{ Å}]; \text{indicating the formation of a weaker hydrogen bonding interaction in MFM-300-} \text{(Ga₁₅₋₇Fe₁₃₋₁₃)} \cdot 2.35\text{CO}_₂. \text{This is consistent with the observed heat of adsorption which also decreases, indicating a weaker interaction between the mixed-metal material and the CO₂ molecule. Given the identical framework structures and pore surface chemistry of MFM-300(Ga) and MFM-300(Ga₁₅₋₇Fe₁₃₋₁₃), this difference in hydrogen bonding is a direct result of Fe-doping into the framework structure. In addition to this hydrogen bond, O₁ also forms weak supramolecular contacts with aromatic hydrogen atoms from the phenyl rings \([\text{O}_1, \cdots \text{H} = 3.055(4), 3.163(5) \text{ Å}, \text{each occurring twice}\]. The CO₂ at site II is disordered over two equally-occupied positions. However, CO₂⁻ adopts a different orientation to that observed in MFM-300(Ga)–2.35CO₂, forming a typical “T-shaped” dipole interaction with CO₂⁻ between the electropositive C center and electronegative O center \([\text{C}_2 \cdots \text{O}_2 = 3.207(6) \text{ Å}, \text{occurring twice}\]. Thus, the small percentage of Fe-doping into this solid solution has a significant effect on the CO₂ binding details, including the formation of both adsorbate–adsorbent hydrogen bonds and adsorbate–adsorbate intermolecular dipole interactions. We could not of course distinguish between Ga and Fe centers in the above experiments, reflecting also the random distribution of Fe within the Ga-based host.

We have thus determined the detailed binding of CO₂ in two isostructural MOFs and have confirmed the formation of hydrogen bonding, C=−H and O=−H supramolecular contacts, and the complementary dipole interactions and cooperative binding of CO₂ molecules within the pores to form one-dimensional chains of CO₂ molecules. In both CO₂-loaded samples, the C=O distances lie within the range 1.176(8)−1.207(5) Å, consistent with typical C=O distances \([1.155(1) \text{ Å}] \text{observed in solid CO₂}. \text{The COC angles in CO₂⁻, CO₂⁺ are } 180°/160(4)° \text{ and } 180°/165(1)° \text{ for MFM-300(Ga)–2.35CO₂ and MFM-300(Ga₁₅₋₇Fe₁₃₋₁₃)} \cdot 2.0CO₂, \text{respectively. The slight bonding of the CO₂⁻ molecules is probably an artifact of the disorder rather than any true distortion in bonding and is comparable to that observed in } [\text{Zn}_2(\text{atz})_2(\text{ox})] \cdot 1.3\text{CO}_₂.\text{ Catalytic Reactions. Two general reactions requiring acid catalysis, namely epoxide ring-opening and the acetylation of benzaldehyde, were selected to determine the influence of the Fe-doping on the catalytic activity of MFM-300(Ga). In the first example, the catalytic activity of as-synthesized MFM-300(Ga) and MFM-300(Ga₁₅₋₇Fe₁₃₋₁₃) was studied in the ring-opening of styrene oxide (1a) with methanol to yield 2-methoxy-2-phenylethanol. In the absence of catalyst, we observed 4% conversion of 1a to 2-methoxy-2-phenylethanol after 30 h at 40 °C. In contrast, the presence of heterogeneous MOF catalyst resulted in significant conversions: MFM-300(Ga) showed 40% conversion of 1a to 2-methoxy-2-phenylethanol in 30 h while MFM-300(Ga₁₅₋₇Fe₁₃₋₁₃) resulted almost in complete conversion of 1a in the same time (Figure 9). Both materials showed no leaching of active sites, as evidenced from the hot filtration test, in which the solid catalyst was removed from the reaction mixture at 40 °C at conversions of about 20% and the clear

![Figure 9](Figure 9. Time conversion plots for the ring-opening of 1a with MeOH using MFM-300(Ga) (black squares) and MFM-300(Ga₁₅₋₇Fe₁₃₋₁₃) (red circles) as catalyst, and ring-opening of 1a with EtOH using MFM-300(Ga₁₅₋₇Fe₁₃₋₁₃) (green triangles) as catalyst.)
solution in the absence of solid was then allowed to react further; no further conversion was then observed after 30 h. The stability of MFM-300(Ga$_{1.87}$Fe$_{0.13}$) as a solid catalyst was studied by cycling it under identical conditions at 40 °C. The percentage conversion of 1a in the first, second, and third cycles was 98, 93 and 83, respectively, in 30 h (Table 2) reflecting some gradual deactivation of the catalyst with time.

| run | catalyst  | time (h) | conversion (%) | selectivity (%) |
|-----|-----------|----------|----------------|-----------------|
| 1   | no catalyst | 30       | 4              | 98              |

"Reaction conditions: 1a (2.08 mmol), catalyst (20 mg) activated at 100 °C for 2 h under vacuum, methanol (5 mL), 40 °C. Determined by GC using nitrobenzene as internal standard. Catalyst filtered at 6 h and the reaction continued to 30 h. \(^{a}\)Catalyst filtered at 3 h and the reaction continued to 30 h. \(^{b}\)Second reuse. \(^{c}\)Third reuse.

We have also studied the reaction of styrene oxide with other alcohols such as ethanol and tert-butanol. As shown in Table 3, MeOH reacts more quickly than EtOH, whereas tert-BuOH showed no reaction even after 30 h. This lack of reactivity with tert-BuOH may be due to the impeded diffusion at low temperature of this larger molecule through the pore system of the MOF, and similar results have been reported for other MOFs and with graphene oxide as heterogeneous catalysts.

| 9   | 1f      | CH$_3$OH     | 24             | 90              |
| 10  | 1h      | CH$_3$OH     | trace          | -               |

\(^{a}\)Reaction conditions: epoxide (0.250 mL), MFM-300(Ga$_{1.87}$Fe$_{0.13}$) activated at 100 °C for 2 h under vacuum (20 mg), methanol (5 mL), 30 h, 40 °C. \(^{b}\)Determined by GC. \(^{c}\)Selectivity refers to 2-methoxycyclohexanol.

The methanolysis of cyclohexene oxide (1b) with MFM-300(Ga$_{1.87}$Fe$_{0.13}$) resulted in 7% conversion with 88% selectivity for the unoptimized catalytic data (2.08 mmol), catalyst (20 mg) activated at 100 °C. The percentage conversion was 24% after 30 h at room temperature (Figure 10). The presence of MFM-300(Ga$_1$) and MFM-300(Ga$_{1.87}$Fe$_{0.13}$) significantly increased the conversion to 1,1-dimethoxycyclohexane. The two catalysts show almost identical activity, as shown by almost identical conversions of 71% and 72%, respectively, at 30 h. MFM-300(Ga$_{1.87}$Fe$_{0.13}$) was also tested in a leaching experiment. The reaction was started in the presence of MFM-300(Ga$_{1.87}$Fe$_{0.13}$), and the solid catalyst was filtered after 4 h with 11% conversion of benzaldehyde. The reaction mixture was then allowed to react further in the absence of catalyst. After 30 h, 39% (instead of 72%) of benzaldehyde was converted, consistent with the expected total conversion for the uncatalyzed reaction based on the data from blank controls in the absence of catalyst. The similar reactivity exhibited by these two MOFs could be followed by in situ IR spectroscopic analysis.
using CO as probe molecule (Figure 11), which showed that both MOFs contained a similar number of active sites. The IR band at 2165 cm\(^{-1}\) could be due to Lewis acid sites, whereas the IR band at 2145 cm\(^{-1}\) is attributed to hydroxyl groups. As confirmed by Figure 11, the majority of the centers interacting with CO are Brönsted acid sites, and since MFM-300(Ga\(_2\)) and MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) have similar populations of acid sites and the demand of acid strength on the benzaldehyde acetalization is low, both solids should exhibit very similar catalytic activity, as is experimentally observed. Differences in catalytic activity between MFM-300(Ga\(_2\)) and MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) are expected for other reactions such as \(\text{S}_2\text{Cl}_2\) epoxide ring-opening, which require higher acid strength. In this way, the combination of spectroscopic titration of acid sites using CO as a probe with the catalytic results for acetylation and epoxide ring-opening indicates that MFM-300(Ga\(_2\)) and MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) have the same population of acid sites, but the presence of Fe-doping increases the acid strength, enabling the use of MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) as catalyst for those reactions requiring sites with higher acid strength. This effect of Fe-doping increasing the strength of the acid sites contrasts with the weaker hydrogen bonding interaction between the framework and CO\(_2\) in single crystals of MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\))·2.0CO\(_2\). It is, therefore, likely that the most active sites in catalysis for MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) are those present in defects, and these will be absent in highly crystalline samples of MFM-300(Ga\(_2\)).

**CONCLUSIONS**

MFM-300(Ga\(_2\)) and the isostructural mixed-metal solid solution MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) were prepared from homogeneous solvothermal reactions. Significant enhancement of CO\(_2\) adsorption capacity by up to 49% was observed by doping with Fe(III), reflecting the increased structural integrity of the Fe-doped material giving a more ordered material with more accessible pores. Thus, Fe-doping can be used to improve the materials properties of the host while also monitoring the effects of the heteroatom center within a parent framework without the requirement of synthesizing the isostructural MFM-300(Fe\(_2\)). *In situ* single-crystal X-ray diffraction studies of CO\(_2\)-loaded materials revealed, on a molecular level, key details into the preferred binding sites within the pores of these materials that were in excellent agreement with the results of the *in situ* polarized IR spectroscopic study of CO\(_2\)-loaded MFM-300(Ga\(_2\)). The adsorbed CO\(_2\) molecules in MFM-300(Ga\(_2\)) hydrogen bond with the free –OH groups on the surface of the pores, and a previously unobserved pattern of intermolecular dipole interactions was found to stabilize the two CO\(_2\) molecules within the pores. The CO\(_2\) molecule at site I binds to the –OH group in an end-on fashion [H···O\(_1\) = 1.883(10) Å] and also interacts with the CO\(_2\) molecule at site II. In contrast, the adsorbed CO\(_2\) molecules in MFM-300(Ga\(_{1.87}\)Fe\(_{0.13}\)) form only very weak hydrogen bonds with free –OH groups [H···O\(_2\) = 2.259(12) Å], and a traditional “T-shaped” CO\(_2\) intermolecular dipole interaction was responsible for the stability of the CO\(_2\) molecular chain. The reduction on the strength of the hydrogen bond is also reflected in the isosteric heat of adsorption for CO\(_2\) uptake. In addition to the enhancement of the gas adsorption properties, Fe-doping has also shown a positive effect on specific catalytic reactions such as the ring-opening reactions of styrene oxide. We anticipate that the strategy developed here, based upon mixing transition and main group metal nodes in MOFs, can lead to the design and discovery of new materials with improved properties and functions.
