We investigated temperature dependent Raman spectra of the one-dimensional spin-ladder compound SrCu$_2$O$_3$. At low temperatures a two-magnon peak is identified at $3160 \pm 10$ cm$^{-1}$ and its temperature dependence analyzed in terms of a thermal expansion model. We find that the two-magnon peak position must include a cyclic ring exchange of $J_{cycl}/J_\perp = 0.09 - 0.25$ with a coupling constant along the rungs of $J_\perp \approx 1215$ cm$^{-1}$ (1750 K) in order to be consistent with other experiments and theoretical results.

PACS numbers: 78.30.-j, 75.50.Ee

Antiferromagnetic copper oxide spin-ladders have been investigated intensively from a theoretical and experimental point of view.\cite{11,12} Superconducting under high pressure\cite{13} they form a bridge between 1D Heisenberg chains and a 2D Heisenberg square-lattice, which is also a model for high-$T_C$ superconductors. The magnetic ground state of a spin ladder is surprisingly not a long ranged Néel state but a short ranged resonating valence bond state\cite{14}. The first excited state is separated from the ground state by a finite energy $\Delta$. The spin gap was first predicted theoretically\cite{15,16} and later confirmed experimentally.\cite{17}

Typical realizations of a two-leg spin-ladder are the compounds SrCu$_2$O$_3$ (Ref.\cite{18}) and (Sr,Ca,La)$_{14}$Cu$_{24}$O$_{41}$\cite{19}. The first compound is a prototype of weakly coupled Cu$_2$O$_3$ spin-ladders while the latter consists of a ladder and a Cu$_2$O edge sharing chain part. In contrast to SrCu$_2$O$_3$, (Sr,Ca,La)$_{14}$Cu$_{24}$O$_{41}$ is intrinsically doped with holes. A schematic view of the compound SrCu$_2$O$_3$ is shown in Fig. 1. Cu atoms, represented by $d$-orbitals, are antiferromagnetically coupled via an intermediate oxygen $p$-orbital by superexchange.\cite{20} The Sr atoms are located in between the planes containing the Cu$_2$O$_3$ atoms. The coupling constants along the legs and the rungs are denoted with $J_\parallel$ and $J_\perp$. The interladder coupling is negligible to first approximation because the superexchange via a Cu-O-Cu path with a 90° bond angle has a smaller orbital overlap than with a bond angle of 180°.\cite{21} Thus, a ladder can be considered an isolated quasi one-dimensional object with a Heisenberg Hamiltonian $H = J_\perp \sum_{\text{rung}} \mathbf{S}_i \cdot \mathbf{S}_j + J_\parallel \sum_{\text{leg}} \mathbf{S}_i \cdot \mathbf{S}_j$. In the literature coupling ratios $J_\parallel/J_\perp \sim 1.7 - 2.0$ have been reported.\cite{11,12} taking the Hamiltonian mentioned above into account for analyzing the data. On the other hand with almost identical Cu-Cu distances in leg and rung direction\cite{22,23} one would expect an isotropic ratio $J_\parallel/J_\perp \sim 1$. This picture was also confirmed by an analysis of optical conductivity data.\cite{24} Recently the inclusion of a cyclic ring exchange $J_{cycl}$ was suggested in order to resolve the discrepancy between the geometrical considerations and $J_\parallel/J_\perp \sim 1.7 - 2.0$.\cite{15,16,17}

This ring exchange can be understood as a superposition of clockwise and counter clockwise permutations of four spins around a plaquette (positions ABCD in Fig. 1). A term $H_{cycl} = J_{cycl} \sum_i K^{\text{ABCD}}_{\text{cycl}}$ with $K^{\text{ABCD}}_{\text{cycl}} = (\mathbf{S}_A\mathbf{S}_B)(\mathbf{S}_C\mathbf{S}_D) + (\mathbf{S}_A\mathbf{S}_D)(\mathbf{S}_B\mathbf{S}_C) - (\mathbf{S}_A\mathbf{S}_C)(\mathbf{S}_B\mathbf{S}_D)$ has to be added to the conventional Heisenberg Hamiltonian $H$.\cite{15} In order to achieve the isotropic limit of $J_\parallel/J_\perp \sim 1$ a ring exchange of $J_{cycl}/J_\perp \sim 0.18 - 0.30$ was introduced.\cite{15,16,17}

In this paper we studied the Raman spectra of the two leg $S = \frac{1}{2}$ spin-ladder compound SrCu$_2$O$_3$. In addition to phonons we investigated the two-magnon peak in this compound at temperatures between 25 K and 300 K. We find that the inclusion of a ring exchange is necessary for the understanding of the magnetic properties of SrCu$_2$O$_3$.\cite{25}

![FIG. 1: Schematic view of the two-leg ladder SrCu$_2$O$_3$ projected on the ab-plane. The Sr atoms are located in between the planes containing the Cu$_2$O$_3$ atoms. The magnetic coupling constants along the rungs and the legs are indicated by $J_\perp$ and $J_\parallel$ and the cyclic ring exchange by $J_{cycl}$. The coupling between two Cu d-orbitals is caused by superexchange interaction via an O p-orbital.](Image)
Polycrystalline SrCu$_2$O$_3$ was grown under high pressure as described by Löffert et al. The crystallographic structure was verified by x-ray diffraction. In addition to SrCu$_2$O$_3$ small amounts of Sr$_2$Cu$_3$O$_5$, CuO and Cu$_2$O were detected. Measurements were performed using a LabRam spectrometer (Dilor) including a grating with 600 and 1800 grooves/mm in backscattering geometry and a multichannel CCD detector. An Ar$^+$ laser spot (488 nm) was focused by a $80 \times$ microscope objective on small individual crystallites on the sample surface with a diameter of 1-2 $\mu$m. The spectra in Fig. 2 were measured at room temperature. The crystallite was chosen by using a polarization microscope. The sample surface was illuminated normally with linear polarized white light. The reflected light was detected through an analyzer crossed to the polarizer with a CCD camera. Being an anisotropic material the reflected light is in general elliptically polarized. As for the ladder compound LaCuO$_2$$_{2,5,20}$ we assume the direction along the ladder ($a$-axis) to be the one with the largest anisotropy in SrCu$_2$O$_3$, whereas the $b$ and $c$ axes are approximately optically isotropic. Thus, there should be a difference in brightness along and perpendicular to the $a$-axis when rotating the sample. If the incident wave vector $\mathbf{k}_i$ is parallel to the $a$-axis the image stays dark while rotating the sample. For $\mathbf{k}_i \perp a$ the crystallite appears dark and bright for four times when turning the sample 360°. The spectra in Fig. 2 were measured on a crystallite for $\mathbf{k}_i \perp a$. For our measurements down to 25 K (spectra in Fig. 3) the sample was mounted on the cold finger of an Oxford microcryostat.

The Raman spectra of SrCu$_2$O$_3$ can be divided into a low (100-1700 cm$^{-1}$) and a high-energy (2000-4600 cm$^{-1}$) region as shown in Figs. 2 and 3. We verified the chemical composition of our polycrystalline sample by an analysis of the phonons in the low energy part of the spectra. We start with a factor group analysis (FGA) of the vibrational modes according to Rousseau et al. The unit cell of SrCu$_2$O$_3$ consists of two formula units. Structure analysis attributes SrCu$_2$O$_3$ to the space group $Cmmm$ ($D_{3h}^{19}$). The FGA results in

$$\Gamma_{\text{SrCu}_2\text{O}_3} = 2A_g + 4B_{1u} + 2B_{1g} + 4B_{2u} + 4B_{3u} + 2B_{3g}$$  (1)

Having a center of inversion only even modes show Raman activity, resulting in six Raman active phonons. We expect the two $A_g$ modes in the spectra measured in parallel polarization while the four even $B$ modes should be observed in crossed polarization.

Figure 2 shows four spectra measured at $T=295$ K two in parallel and two in crossed polarization. The axes were identified using the described analysis with polarized light; comparing Fig. 2 to the spectra of the very similar ladder compound Sr$_{14}$Cu$_{24}$O$_{41}$, we identify the $a$ (leg) and $b$ (rung) axes as indicated in the figure. In $(bb)$ polarization only a single phonon at 550 cm$^{-1}$ is observed, while in $(aa)$ two phonons at 310, 550 cm$^{-1}$, and in addition several broad peaks around 1150 cm$^{-1}$ are visible. We assign these two phonons as the two allowed $A_g$ modes. In Sr$_{14}$Cu$_{24}$O$_{41}$ modes at 316 cm$^{-1}$ and 549 cm$^{-1}$ were observed. The latter is believed to be the breathing mode of the O-ladder atoms located on the ladder legs, which is in accordance with our assignment. The structure at about 1150 cm$^{-1}$ was also observed in Sr$_{14}$Cu$_{24}$O$_{41}$, its origin attributed to two-phonon processes. Knowing only few phonons at the $\Gamma$ point the details of the broad structure around 1150 cm$^{-1}$ in SrCu$_2$O$_3$ remain unclear. In summary, we identified the two allowed $A_g$ ladder phonons at 310 and 550 cm$^{-1}$ in SrCu$_2$O$_3$ at room temperature, the $B_{3g}$ modes were too weak to be observed, and the $B_{3g}$ not allowed for our geometry.

In Fig. 2 in addition to the phonons a peak around 3000 cm$^{-1}$ was observed in $(aa)$ and $(bb)$ polarizations while it was absent in the crossed polarizations $(ab)$ and $(ba)$. It can be shown from the two-magnon Raman Hamiltonian that for a two-leg Heisenberg ladder the two-magnon peak is forbidden in all crossed polarizations. The observed spectra follow the selection rules of a two-magnon peak.

In Fig. 3 the Raman spectra of the high-energy region are presented for different temperatures. The spectra were measured on another crystallite between 25 K and 300 K. Comparing them to the aligned spectra in Fig. 2 we assign the upper spectrum as $(aa)$ and the lower one as $(bb)$ polarized. In $(aa)$ polarization a sharp peak is visible which broadens and shifts to lower energies.
with increasing temperature. In (bb) polarization a much broader peak is measured; it remains broad also down to the lowest temperatures. We identify these features to be the two-magnon peaks which were also observed in Sr$_{14}$Cu$_{24}$O$_{44}$ at a lower energy (maximum for $T=8$-20 K at 2900-3000 cm$^{-1}$). The energy of the peak maxima as a function of temperature is shown in the upper inset of Fig. 3. In (bb) polarization the left edge position is plotted as a function of temperature in the lower insets of Fig. 3 due to difficulties in determining the precise peak maxima. The two-magnon peak shifts for $T>75$ K almost linearly with temperature and saturates at low temperatures at 3160 cm$^{-1}$ (peak position) and 3130 cm$^{-1}$ (edge position).

Using a simple model of thermal expansion we are able to understand the temperature dependence of these peaks. The starting point is a system containing two copper $d$-orbitals and one intermediate oxygen $p$-orbital with a $180^\circ$ bond angle as found in flat ladder compounds, hence the model is not only applicable to SrCu$_2$O$_3$ but also, e.g., to Sr$_{14}$Cu$_{24}$O$_{44}$. The two copper atoms are coupled by superexchange with the coupling constant $J$. We assume that the two-magnon energy scales linearly with $J$. The average distance $d$ between two copper atoms is a function of temperature. Due to an anharmonic interatomic potential the average distance increases in first order as $d = d_0 + A\omega/(\exp(\omega/T) - 1)$, where $d_0$ is the distance at $T=0$ K, $A$ is a constant, representing the strength of the expansion, and $\omega$ is an averaged phonon energy (Einstein model). Within the three-band Hubbard-model $J$ equals $4t_{pd}^2/(\varepsilon_{pd}^2(U_d^{-1} + \varepsilon_{pd}^{-1})$ with $t_{pd}$ being the overlap integral between Cu-O sites, $U$ the Coulomb repulsion, and $\varepsilon_{pd}$ the charge transfer energy.

The temperature dependence of the two-magnon energy, which is proportional to $J$, arises from a Taylor expansion around $d_0$.

$$E_{2-mag} = E_0 - \frac{B\omega}{\exp(\omega/T) - 1}$$

$E_0$ is the two-magnon energy at $T=0$ K, $B$ is a dimensionless constant proportional to $A$, and $\omega$ is the averaged phonon frequency. Other power-law exponents in Eq. (2) have been used in similar systems in the literature (e.g., Kawada et al.); the further analysis does not depend much on this choice as long $B$ is simply a parameter. The temperature dependence of the peak/edge maxima of both spectra in the insets of Fig. 3 were fitted simultaneously using Eq. (3) with the parameters $B=0.94 \pm 0.05$, $\omega = 160 \pm 10$ cm$^{-1}$, $E_0(aa) = 3160 \pm 10$ cm$^{-1}$ and $E_0(bb) = 3130 \pm 10$ cm$^{-1}$. The fit shows excellent agreement with the experimental data. The averaged phonon frequency $\omega$ is comparable to those of high-$T_C$ cuprate materials. The different values for $E_0$ in the (aa) and (bb) spectra in Fig. 3 are caused by the difference between peak edge and peak maximum. For the further analysis we take only the energy $E_0(aa)=3160$ cm$^{-1}$ into account. The observed temperature dependence is in accordance with the assumed magnetic origin of the peak. The common picture of superexchange is confirmed by our measurements.

We now show that in order to compare the energy $E_0$ with existing experiments and theoretical results in a consistent way the cyclic ring exchange must be included. Note, that it is not possible to determine the magnetic constants and the spin gap directly from the two-magnon peak position. In order to obtain these values from our spectra we have to make several assumptions based on calculations: (i) $Ab\ initio$ calculations$^{10}$ yielded $J_{\parallel}/J_\perp = 1.1$ for the coupling constant ratio. This ratio is also close to the isotropic limit, which can be deduced from geometrical considerations. (ii) We include a ring exchange of $J_{cycl}/J_\perp = 0.09 - 0.25$. Cyclic ring exchange values on the same order ($J_{cycl}/J_\perp = 0.18 - 0.30$) have also been introduced for the comparable two-leg spin ladder compound (La,Ca)$_2$LaCu$_2$O$_{11}$ (Refs. 16,17). (iii) Schmidt et al. have shown recently in a theoretical Raman study for a Heisenberg two-leg ladder with $J_{\parallel}/J_\perp = 1.2$ and $J_{cycl}/J_\perp = 0.2$ that the two-magnon peak maximum should be located at $E_0 \approx 2.6 \cdot J_\perp$ \cite{32}. Because the ratio $J_{\parallel}/J_\perp = 1.2$ is slightly larger than the...
one stated above for SrCu$_2$O$_3$ we take $E_0/J_\perp = 2.6 \pm 0.1$ for a further analysis. (iv) Calculating the spin gap we use the expression $\Delta \approx 0.48 \cdot J_\perp - 1.08 \cdot J_{cycl}$ which has been derived by Nunner et al.\textsuperscript{24} for a two-leg Heisenberg ladder with ring exchange having adjusted for the different definitions of $J_{cycl}$. The expression for $\Delta$ is valid approximately in the range $J_\parallel/J_\perp = 1.0 - 1.3$. As a result we obtain from our experiment $J_\parallel = 1170 - 1260$ cm$^{-1}$ ($1680 - 1810$ K) for the coupling constant. Taking $J_\perp = 1215$ cm$^{-1}$ results in $\Delta = 260 - 470$ cm$^{-1}$ ($380 - 680$ K) for the spin gap. The latter value is in good agreement with spin gap values measured with susceptibility ($420$ K)\textsuperscript{25} NMR ($680$ K)\textsuperscript{26} and neutron scattering ($380$ K)\textsuperscript{11} on Sr$_{14}$Cu$_{24}$O$_{41}$.\textsuperscript{11} In contrast, excluding the spin exchange coupling would yield a spin gap value of approximately $840$ K, which is out of scale by a factor of 1.2 - 2.2 when comparing to the experiments mentioned. Our experiment thus supports the presence of a four spin ring exchange on the order of $J_{cycl}/J_\perp = 0.09 - 0.25$. The lower limit of $J_{cycl}/J_\perp$ so obtained corresponds to $\Delta$ from NMR, the upper one to $\Delta$ from neutron scattering.

In conclusion we found the two allowed $A_g$ phonons at $310$ cm$^{-1}$ and $550$ cm$^{-1}$ in SrCu$_2$O$_3$ and studied the magnetic excitations in this compound. A peak with an energy of $3160 \pm 10$ cm$^{-1}$ at low temperatures starts to shift to lower energies with increasing temperature. We identified this peak as the two-magnon peak and confirmed this by its temperature dependence. We derived a simple expression which describes excellently the peak energy as a function of temperature. For low temperatures we are able to explain the two-magnon peak energy $E_0=3160$ cm$^{-1}$ in accordance with existing theoretical and experimental results by including a cyclic ring exchange using the values: $J_\parallel/J_\perp = 1.1$, $J_{cycl}/J_\perp = 0.09 - 0.25$, $J_\perp \approx 1215$ cm$^{-1}$ ($1750$ K) and $\Delta=260-470$ cm$^{-1}$ ($380 - 680$ K).

We thank K. P. Schmidt and G. S. Uhrig for helpful and valuable discussions. This work was supported by the Deutsche Forschungsgemeinschaft, SPP 1073.
