Population-based characteristics of fatal and hospital admissions for poisoning in Fiji: TRIP Project-11

Roshini Peiris-John,1 Berlin Kafoa,2 Iris Wainiqolo,2 Ravi Krishnan Reddy,3 Eddie McCaig,4 Shanthi N Ameratunga1

ABSTRACT
This study investigated the incidence and characteristics of poisoning fatalities and hospital admissions among indigenous Fijians and Indians in Viti Levu, Fiji. Individuals with a mechanism of injury classified as poisoning were identified using the Fiji injury surveillance in hospitals system, a population-based registry established for 12 months in Viti Levu, and analysed using population-based denominators. The mean annual rates of fatalities and hospitalisations were 2.3 and 26.0 per 100 000, respectively. Over two-thirds of poisonings occurred among people of Indian ethnicity. Most intentional poisoning admissions occurred among women (58.3%) and in 15–79-year-old individuals (73.8%). Unintentional poisoning admission rates were highest among Indian boys aged 0–14 years. While over 75% of events occurred at home, the substances involved were not systematically identified. The findings indicate the need for a strategy that addresses the differing contexts across age group, gender and ethnicity, and a lead agency responsible for implementing and monitoring its effectiveness.

METHODS
The Fiji injury surveillance in hospitals system was established at all hospitals in Viti Levu for 12 months commencing 1 October 2005 as part of the Traffic-Related Injury in the Pacific (TRIP) project. This population-based registry, the development of which has been described previously,12 captured data on all deaths and hospital admissions for more than 12 h due to an acute injury or poisoning. Cases were identified from hospital accident and emergency registers, admission and post-mortem records. All poison-related deaths in Fiji are reported to the Police department and undergo postmortem examination. This study focused on all records in the Fiji injury surveillance in hospitals database in which the mechanism of injury was classified as poisoning. Population-based incidence rates by sociodemographic characteristics were computed using denominator data from the Fiji census of 2007. The unique national hospital numbers were used to avoid double-counting of events.

RESULTS
Fatalities
The 17 deaths (nine men) corresponded to an annual fatality rate of 2.3 per 100 000 population. All but one death was deemed intentional, most involving people of Indian ethnicity (n=13) and the age group 15–29 years (n=12). Most events (n=14) occurred at home or in a private compound. Five deaths occurred out of hospital, and 12 followed admission with an in-hospital case fatality rate of 7.1% (12/169).

Non-fatal hospitalisations
The 157 non-fatal hospitalisations accounted for an annual rate of 24.1 per 100 000 population in Viti Levu. Poisonings deemed intentional, unintentional and of undetermined intent accounted for 53.5%, 43.9% and 2.5% of non-fatal events. The annual rate for intentional and unintentional poisoning was 12.9 and 10.6 per 100 000 population, respectively.

Female patients accounted for 58.3% of intentional poisonings and male patients accounted for 56.5% of unintentional events. While 73.8% of the intentional poisoning patients were in the 15–29 year age group, 40.6% of unintentional injury deaths occurred among children aged 14 years or less. The mean length of hospital stay was 2.6 days (median 2.0). Most poisoning events that resulted in non-fatal hospital admissions (93.6%) occurred at home or in a private compound.
Among the people who were admitted for poisoning, 107 (68.2%) were of Indian ethnicity, 47 (29.9%) were Fijian and three (1.9%) were of other ethnicities. The crude annual rate of non-fatal hospitalisations due to poisoning among Indians was three times that of Fijians (41.2 vs 13.3, per 100 000 population). Most non-fatal admissions among the Fijians were due to unintentional poisoning, while the majority of admissions and fatalities among Indians were due to intentional poisoning (table 1).

The context for unintentional poisoning events was commonly reported as ‘leisure or play’ (Fijians 94.3%, Indians 72.7%). Rates were highest among Indian boys aged 0–14 years (figure 1). The context for intentional poisoning events was most commonly reported as a conflict situation (Fijians 100%, Indians 93%). The age group most commonly involved was 15–29 years, with rates for women and men being considerably higher for Indians (116.6 and 70.0 per 100 000, respectively). Equivalent rates among Fijian women and men were 11.9 and 9.8 per 100 000, respectively.

Substances involved

Only a third of clinical records documented the substance involved in poisonings, a factor that did not differ significantly by age, gender, ethnicity, intent or outcome (fatal or non-fatal). Among intentional poisonings, the commonly documented substances were chemicals (41.2%), drugs (35.3%) and pesticides (23.5%). In unintentional poisonings, chemicals (69.6%), food (21.7%) and drugs (8.7%) comprised the common sources. The ‘chemicals’ involved were typically not defined further but kerosene and household cleaning products were identified as the agent in several (11) cases. Two cases were ascribed to ciguatera fish poisoning.

DISCUSSION

This study adds to the relatively sparse published epidemiological information on poisoning in Pacific Islands by identifying a population-based profile of acute poisoning fatalities and hospital admissions in Viti Levu, Fiji. Over two-thirds of events in this predominantly Melanesian country occurred among people of Indian ethnicity. Rates of intentional poisoning were particularly high among Indian women aged 15–29 years, while unintentional poisoning rates were highest among Indian boys aged 0–14 years.

The use of a quality-assured injury surveillance database that captured serious poisoning events resulting in hospital admission or death provided the opportunity to obtain population-based estimates in this setting and identify subgroups at increased risk of poisoning. When interpreting findings, however, it is important to acknowledge that access to health-care could influence presentations, and the study was not designed to identify assessments by primary care providers or traditional healers. The study is also limited by the lack of detailed information on the context of these events and systematically coded data on the substances involved. In the third of cases in which this information was available, the minimum dataset available did not characterise the types of ‘chemicals’ or ‘drugs’ involved. Consistent with many developing countries, pesticides and drugs were commonly implicated in intentional poisoning. The study focused on Viti Levu where over 70% of the population resides, and the epidemiology of poisoning was not considered likely to be substantially different in other parts of Fiji. However, the relatively small study population could lead to a degree of imprecision in the estimates derived.

The rate of attempted suicide by poisoning in a previous hospital-based study in Fiji was twice that estimated in our study (25.9 compared with 12.9 per 100 000). This difference is likely to be due to the exclusion of patients admitted for less than 12 h and the inclusion of the entire population of Viti Levu in the present study. The higher rate of poisoning deemed intentional, with women aged 15–29 years being at highest risk, is a pattern observed in many low and middle-income countries including Ethiopia, Iran, India, Nepal and Malaysia.

While the absolute numbers of deaths were low and crude mortality rates were difficult to compare due to different demographic structures, the inhospital case fatality rate in Viti Levu (7.1%) is similar to findings in Ethiopia (8.6%), but higher than those reported from Iran (1.3–2.3%) and Nepal (5%). However, higher case fatality rates have been reported from India (12.8–15%).

The ethnic differences identified in our study are consistent with previous case series from Fiji and the observation of elevated rates of suicide among the Indian diaspora in other countries. While the context is likely to be complex, a range of sociocultural and behavioural factors have been postulated, including the high social mobility, breakdown in the extended family system and rapid cultural transformation as well as impulsivity, aggression and easy accessibility to agents such as pesticides. The findings of this study indicate the need for careful explorations of the physical and sociocultural environments in which these events occur. Aspects that may differ among age group, gender and ethnic lines that require particular attention in an overarching poison control strategy include the exposure to hazardous substances during the developmentally vulnerable

| Table 1 | Characteristics of non-fatal hospitalisations for poisoning by ethnicity |
|---|---|---|---|---|
| No (%) of | Gender | Fijians (n=47) | Indians (n=107) | \( \chi^2 \) Value (p value) |
| | Male | 23 (48.9) | 50 (46.7) | 0.06 (0.800) |
| | Female | 24 (51.1) | 57 (53.3) | 0.06 (0.800) |
| Age group, years | 0–14 | 14 (29.8) | 18 (16.8) | 12.90 (<0.005) |
