Role of anticonvulsant and antiepileptogenic neurosteroids in the pathophysiology and treatment of epilepsy

This review highlights the role of major endogenous neurosteroids in seizure disorders and the promise of neurosteroid replacement therapy in epilepsy. Neurosteroids are endogenous modulators of seizure susceptibility. Neurosteroids such as allopregnanolone (3α-hydroxy-5α-pregnane-20-one) and allotetrahydrodeoxycorticosterone (3α,21-dihydroxy-5α-pregnane-20-one) are positive modulators of GABA-A receptors. Aside from peripheral tissues, neurosteroids are synthesized within the brain, mostly in principal neurons. Neurosteroids potentiate synaptic GABA-A receptor function and also activate δ-subunit-containing extrasynaptic GABA-A receptors that mediate tonic currents and thus may play an important role in neuronal network excitability and seizure susceptibility. Our studies over the past decade have shown that neurosteroids are broad-spectrum anticonvulsants and confer seizure protection in various animal models. They protect against seizures induced by GABA-A receptor antagonists, 6-Hz model, pilocarpine-induced limbic seizures, and seizures in kindled animals. Unlike benzodiazepines, tolerance does not occur to their actions during chronic administration. Our recent studies provide compelling evidence that neurosteroids may have antiepileptogenic properties. There is emerging evidence that endogenous neurosteroids may play a key role in the pathophysiology of catamenial epilepsy, stress–sensitive seizure conditions, temporal lobe epilepsy, and alcohol-withdrawal seizures. It is suggested that neurosteroid replacement with natural or synthetic neurosteroids may be useful in the treatment of epilepsy. Synthetic analogs of neurosteroids that are devoid of hormonal side effects show promise in the treatment of diverse seizure disorders. Agents that stimulate endogenous production of neurosteroids may also be useful for treatment of epilepsy.

INTRODUCTION

Neurosteroids are steroids synthesized within the brain with unconventional rapid effects on neuronal excitability. It is well known that steroid hormones such as progesterone and deoxycorticosterone can exert anticonvulsant actions (Selye, 1941; Clarke et al., 1973). The anticonvulsant properties of progesterone and deoxycorticosterone are predominantly due to their conversion in the brain to neurosteroids allopregnanolone (3α-hydroxy-5α-pregnane-20-one) and allotetrahydrodeoxycorticosterone (3α,21-dihydroxy-5α-pregnane-20-one; THDOC), respectively (Reddy, 2003; Reddy et al., 2004; Figure 1). A variety of neurosteroids are known to be synthesized in the brain (Baulieu, 1981; Kulkarni and Reddy, 1995). The most widely studied are allopregnanolone, THDOC, and androstanediol. These neurosteroids are produced via sequential A-ring reduction of the steroid hormones by 5α-reductase and 3α-hydroxysteroid-oxidoreductase isoenzymes (Reddy, 2009a). The androgenic neurosteroid androstanediol (5α-androstan-3α,17β-diol; Figure 1) is synthesized from testosterone (Reddy, 2004a,b). Other neurosteroids such as 7α-hydroxypregnanolone have been reportedly synthesized in the brain (Tsutsui et al., 2010). In the periphery, the steroid precursors are mainly synthesized in the gonads, adrenal gland, and feto-placental unit, but synthesis of these neurosteroids likely occurs in the brain from cholesterol or from peripherally derived intermediates. Since neurosteroids are highly lipophilic and can readily cross the blood–brain barrier, neurosteroids synthesized in peripheral tissues accumulate in the brain (Reddy and Rogawski, 2010a).

Recent evidence indicates that neurosteroids are present mainly in principal neurons in many brain regions that are relevant to focal epilepsies, including the hippocampus and neocortex (Agis-Balboa et al., 2006; Saalmann et al., 2007; Do Rego et al., 2009). The biosynthesis of neurosteroids is controlled by the translocator protein (18 kDa; TSPO), formerly called peripheral or mitochondrial benzodiazepine receptor (Rupprecht et al., 2009, 2010). Activation of TSPO by endogenous signals and ligands facilitates the intramitochondrial flux of cholesterol and thereby promotes neurosteroid synthesis. It is suggested that TSPO ligands might be an alternative approach for neurosteroid therapeutics (Nothdurfter et al., 2011). Currently, synthetic analogs of endogenous neurosteroids are under clinical trial for treatment of epilepsy (Reddy and Rogawski, 2010a).
This review describes the pathophysiological role of major endogenous neurosteroids in seizure disorders and the promise of neurosteroid replacement therapy in epilepsy. This review also summarizes the current status of synthetic neurosteroids and their therapeutic potentials. The main focus of the review is on GABAergic neurosteroids with anticonvulsant activity. Endogenous neurosteroids, such as pregnenolone, pregnenolone sulfate, and dehydroepiandrosterone sulfate, which promote neuronal excitability and seizures, are not discussed here because such description is beyond the scope of this article. The paradoxical effect of allopregnanolone are discussed elsewhere (Bäckström et al., 2011).

**OVERVIEW OF NEUROSTEROID POTENTIATION OF GABA-A RECEPTORS**

Neurosteroids rapidly alter neuronal excitability through direct interaction with GABA-A receptors (Harrison and Simmonds, 1984; Majewska et al., 1986; Harrison et al., 1987; Gee et al., 1988; Hosie et al., 2007, 2009), which are the major receptors for the inhibitory neurotransmitter GABA. Activation of the GABA-A receptor by various ligands leads to an influx of chloride ions and a hyperpolarization of the membrane that dampens the excitability. Allopregnanolone and other structurally related neurosteroids act as positive allosteric modulators and direct activators of GABA-A receptors (Figure 2). At low concentrations, neurosteroids potentiate GABA-A receptor currents, whereas at higher concentrations, they directly activate the receptor (Harrison et al., 1987; Reddy and Rogawski, 2002). Like barbiturates, neurosteroid enhancement of GABA-A receptors occurs through increases in both the channel open frequency and channel open duration (Twyman and Macdonald, 1992; Lambert et al., 2009; Ramakrishnan and Hess, 2010).

The GABA-A receptor is a pentamer consisting of five subunits that form a chloride channel. Sixteen subunits (α1-6, β1-3, γ1-3, δ, ε, θ, and π subunits) have been identified so far. The GABA site is located at the interface between α and β subunits. Benzodiazepines bind at the interface between α and γ subunits and they interact with subunit combinations α1,2,3,5β2γ2. The effect of neurosteroids on GABA-A receptors occurs by binding to discrete sites on the receptor–channel complex that are located within the transmembrane domains of the α- and β-subunits (Hosie et al., 2006, 2007), which they access by lateral membrane diffusion (Chisari et al., 2009, 2010). The binding sites for neurosteroids are distinct from the recognition sites for GABA, benzodiazepines, and barbiturates (Hosie et al., 2009). Androgenic neurosteroids such as androstane dioxide may interact with these sites, and a recent study indicates that this agent is a positive allosteric modulator of GABA-A receptors (Reddy and Jian, 2010). In whole-cell recordings from acutely dissociated hippocampus CA1 pyramidal cells in mice, androstane dioxide (not its 3β-epimer) produced a concentration-dependent enhancement of GABA-activated currents (EC50 = 5 μM). At 1 μM, androstane dioxide produced a 50% potentiation of GABA responses. In the absence of GABA, androstane dioxide has modest direct effects on GABA-A receptor-mediated currents even at high concentrations, indicating that it has lower direct efficacy than allopregnanolone and THDOC.

Although neurosteroids act on all GABA-A receptor isoforms, they have large effects on extrasynaptic δ-subunit-containing GABA-A receptors that mediate tonic currents (Belelli et al., 2002; Wohlfarth et al., 2002). The potentiation of δ-subunit-containing receptors by THDOC and other neurosteroids is selective for channels with low-efficacy gating characteristics marked by brief bursts and channel openings in conditions of both low and high GABA concentrations, and neurosteroids can thereby preferentially increase the efficacy of these receptors based on
pharmacokinetics which are not yet fully understood (Bianchi and Macdonald, 2003). Neurosteroids therefore markedly enhance the current generated by δ-subunit-containing receptors even in the presence of saturating GABA concentrations. Consequently, GABA-A receptors that contain the δ-subunit are highly sensitive to neurosteroid potentiation and mice lacking δ-subunits show drastically reduced sensitivity to neurosteroids (Mihalek et al., 1999; Spigelman et al., 2002). Tonic current causes a steady inhibition of neurons and reduces their excitability. Neurosteroids therefore could play a role in setting the level of excitation by potentiation of tonic inhibition during seizures when ambient GABA rises (Stell et al., 2003). This phenomenon is being investigated to characterize the developmental and physiological implications of neurosteroid activation of tonic currents in the hippocampus and other areas.

The GABA-A receptor mediates two types of GABAergic inhibition, now stratified into synaptic (phasic) or extrasynaptic (tonic) inhibition (Figure 2). Although GABA activates synaptic (γ2-containing) GABA-A receptors with high efficacy, GABA activation of the extrasynaptic (δ-containing) GABA-A receptors are limited to low-efficacy activity characterized by minimal desensitization and brief openings. Physiological tonic currents of GABA receptors are dependent on the pentamer subunit composition and fairly independent of physiological levels of ambient, exogenous GABA (McCartney et al., 2007; Ransom et al., 2010). The high sensitivity of δ-containing receptor channels to neurosteroid modulation may be dependent on the δ-subunit or the low-efficacy channel function that it confers. There is evidence that neurosteroids preferentially enhance low-efficacy GABA-A receptor activity independent of subunit composition (Bianchi and Macdonald, 2003). Gaboxadol also modulates δ-subunit receptor isoforms at higher concentrations, acting as a superagonist, resulting in an induced higher efficacy gating pattern than either GABA or muscimol (Mortensen et al., 2010). Novel therapeutic approaches are being developed based on the emerging information on neurosteroid interaction with GABA-A receptors (Murashima and Yoshi, 2010).

Some endogenous neurosteroids are known to interact with GABA-A receptor and block its inhibitory function. Such neurosteroids include pregnenolone, pregnenolone sulfate (PS), dehydroepiandrosterone, and dehydroepiandrosterone sulfate (DHEAS). PS inhibits the GABA-A receptor function, and is also moderately potent allosteric agonist at NMDA receptors (Wu et al., 1991; Majewska, 1992). PS and DHEAS are proconvulsant steroids and can induce seizures when administered systemically or directly into the brain (Reddy and Kulkarni, 1998; Kokate et al., 1994; Frye, 1995; Wieland et al., 1995; Reddy et al., 2007). The proconvulsant actions of PS are evident at micromolar concentrations, which are 100- to 500-fold higher than its levels in the brain. Thus, it is highly unlikely that endogenous PS by itself can trigger seizures. However, PS can decrease GABAergic inhibitory transmission at physiological concentrations via a presynaptic action (Teschemacher et al., 1997; Mitchellshvili and Kapur, 2003). Allopregnanolone blocks the seizure facilitating effects of PS and DHEAS, and consequently, these sulfated neurosteroids could contribute to seizure susceptibility when allopregnanolone and THDOC levels are low.

### Table 1 | Antiseizure profile (ED50 values) of endogenous neurosteroids in animal seizure models.

| Seizure model                      | Allopregnanolone | THDOC | Androstanediol |

The potency of neurosteroids is expressed in terms of ED50, which is the dose in mg/kg producing seizure protection in 50% of animals. Values in parentheses are 95% confidence limits. ND, not determined. **Considered as inactive because of such high (sedative or anesthetic) doses.

### Anticonvulsant activity of neurosteroids

Allopregnanolone-like neurosteroids are powerful anticonvulsants. Exogenously administered neurosteroids, like other agents that act as positive GABA-A receptor modulators, exhibit broad-spectrum anticonvulsant effects in diverse rodent seizure models (Reddy, 2010). Neurosteroids protect against seizures induced by GABA-A receptor antagonists, including pentylentetrazol and bicuculline, and are effective against pilocarpine-induced limbic seizures and seizures in kindled animals (Bellei et al., 1989; Kokate et al., 1994; Frye, 1995; Wieland et al., 1995; Reddy et al., 2004). Like other GABAergic agents, they may exacerbate generalized absence seizures (Snead, 1998; Citraro et al., 2006). As shown in Table 1, the potencies of neurosteroids in models where they confer seizure protection vary largely in accordance with their activities as positive allosteric modulators of GABA-A receptors. Thus, allopregnanolone is roughly equally potent as THDOC, but androstanediol and androsterone are somewhat less potent (Reddy, 2004ab; Kaminski et al., 2005). Like other GABAergic agents, neurosteroids are inactive or only weakly active against seizures elicited by maximal electroshock. Neurosteroids are highly active in the 6-Hz model, a better paradigm in which limbic-like seizures are induced by electrical stimulation of lower frequency and longer duration than in the maximal electroshock test (Kaminski et al., 2004). Androstanediol, but not its 3β-epimer, produced a dose-dependent suppression of behavioral and electrographic seizures in the mouse hippocampus kindling (Reddy and Jian, 2010). The estimated concentrations of androstanediol producing 50% seizure protection in the kindling model (~10μM)
are within the range of concentrations that potentiate GABA-A receptor function in CA1 pyramidal neurons.

In addition, neurosteroids are also highly effective in suppressing seizures due to withdrawal of GABA-A receptor modulators including neurosteroids and benzodiazepines, as well as other types of agents such as ethanol and cocaine (Devaud et al., 1996; Tsuda et al., 1997; Reddy and Rogawski, 2001). In contrast to benzodiazepines, where utility in the chronic treatment of epilepsy is limited by tolerance, anticonvulsant tolerance is not evident with neurosteroids (Kokate et al., 1998; Reddy and Rogawski, 2000a). Thus, neurosteroids have the potential to be used in the chronic treatment of epilepsy. Unlike benzodiazepines, neurosteroids are able to modulate all isofoms of GABA-A receptors, including those that contain benzodiazepine-insensitive α4 and β6 subunits or lack the obligatory γ2 subunit required for benzodiazepine-sensitivity. Thus, it is clear that neurosteroids can act on GABA-A receptors where the proposed benzodiazepine tolerance mechanisms have been invoked by chronic GABAergic drug therapy or other endogenous conditions. Surprisingly, while chronic neurosteroid exposure does not lead to anticonvulsant tolerance, neurosteroid exposure does lead to tolerance for benzodiazepines (Reddy and Rogawski, 2000a). Thus, it appears that the same plastic changes that underlie benzodiazepine tolerance are brought into play by chronic neurosteroid exposure. However, neurosteroids acting at distinct sites on GABA-A receptors and exhibiting effects on the full range of GABA-A receptor isofoms, do not exhibit anticonvulsant tolerance. Overall, neurosteroids are more robust anticonvulsants than benzodiazepines.

**ANTIEPILEPTOGENIC ACTIVITY OF NEUROSTEROIDS**

In addition to anticonvulsant activity, there is emerging evidence that endogenous neurosteroids play a role in regulating epileptogenesis (Edwards et al., 2001; Biagini et al., 2006, 2009, 2010; Reddy et al., 2010). The term “epileptogenesis” is used to describe the complex plastic changes in the brain that, following a precipitating event, convert a normal brain into a brain debilitated by recurrent seizures (Pitkänen et al., 2009). Limbic epilepsy is caused by diverse precipitating factors such as brain injury, stroke, infections, or prolonged seizures. Using the kindling model, we demonstrated that the development and persistence of limbic epileptogenesis are impaired in mice lacking progesterone receptors (Reddy and Mohan, 2011). To explore mechanisms underlying the observed seizure resistance, we investigated the role of neurosteroids using finasteride, a 5α-reductase inhibitor that blocks the synthesis of progesterone-derived neurosteroids. We determined the rate of rapid kindling in both control animals and those which had received injections of progesterone with or without concurrent finasteride treatment (Figure 3A). Progesterone produced a significant delay in the rate of kindling and pretreatment with finasteride blocked progesterone’s inhibition of kindling epileptogenesis. These findings are consistent with a contributory role of neurosteroids in limbic epileptogenesis. Thus, it is possible that inhibition of neurosteroids could incite mechanisms that may promote epileptogenesis.

Following pilocarpine-induced status epilepticus (SE) in the rat, the neurosteroidogenic enzyme P450scs is upregulated for several weeks, suggesting that it may be associated with promotion of neurosteroidogenesis (Biagini et al., 2009). Ordinarily, rats develop spontaneous recurrent seizures following a latent period of similar duration to the period during which P450scc is elevated. Inhibiting neurosteroid synthesis with finasteride accelerated the onset of spontaneous recurrent seizures (Biagini et al., 2006), suggesting that endogenous neurosteroids play a role in restraining epileptogenesis or at least that they inhibit the expression of seizures.

The development of epilepsy is linked to complex alterations in neuroplastic mechanisms. Dysregulation of neurosteroid synthesis may also play a role. This premise is being tested in various epileptogenic models (Reddy and Mohan, 2011). We investigated the role of the prototype endogenous neurosteroid allopregnanolone in controlling limbic epileptogenesis. Treatment with finasteride, a neurosteroid synthesis inhibitor, resulted in a significant increase in epileptogenesis in the hippocampus kindling model. Exogenous administration of allopregnanolone, at doses that produce levels similar to gonadotropins, markedly inhibited...
epileptogenesis. Based on these pilot studies, it is suggested that augmentation of neurosteroid synthesis may represent a unique strategy for preventing or retarding epileptogenesis. Exogenous treatment with neurosteroids or with progesterone (P), which serves as a precursor for neurosteroid synthesis, has also been reported to delay the occurrence of epileptogenesis (Reddy et al., 2010). P targets multiple molecular and cellular mechanisms relevant to epileptogenesis including signaling cascades of inflammation, apoptosis, neurogenesis, and synaptic plasticity (Roof and Hall, 2006; Patel, 2004; Vezzani, 2005; Meffre et al., 2007; Stein and Sayeed, 2010). Therefore, P may be a natural disease-modifying agent. However, the potential disease-modifying effect of P in epileptogenic models is not widely investigated. Recently, we examined the effects of P on the development of hippocampus kindling in rodent models (Reddy et al., 2010). P significantly suppressed the rate of development of behavioral kindled seizure activity evoked by daily hippocampus stimulation at doses that do not significantly affect seizure expression and motor performance (Figure 3B), indicating a disease-modifying effect of P on limbic epileptogenesis. There was a significant increase in the rate of "rebound or withdrawal" kindling during drug-free stimulation sessions following abrupt discontinuation of P treatment. A washout period after termination of P treatment prevented such acceleration in kindling. These studies suggest that P exerts disease-modifying effects in the limbic epileptogenesis and it is likely that this effect of P may occur partly through neurosteroid mechanisms. Thus, it is likely that neurosteroids themselves or modulators of neurosteroid disposition could potentially have disease-modifying therapeutic activity.

**ROLE OF ENDOGENOUS NEUROSTEROIDS IN EPILEPSY**

Neurosteroids may play a key role in the physiological regulation of seizure susceptibility in individuals with epilepsy. Endogenous neurosteroids may affect seizures situations in catamenial epilepsy, stress, temporal lobe epilepsy (TLE), and alcohol withdrawal (Reddy, 2009a; Kim et al., 2010). However, it is noteworthy that there is no evidence that alterations in neurosteroid levels in the absence of preexisting epilepsy can induce epileptogenesis. Indeed, 5α-reductase inhibitors such as finasteride, which are widely used clinically for the treatment of benign prostatic hypertrophy and male pattern hair loss, effectively inhibit neurosteroidogenesis. Increased incidence of seizures is not evident in patients taking finasteride. Nevertheless, it is possible that alterations in neurosteroidogenesis may play a role as inciting factors in the development and persistence of limbic epilepsy (Reddy and Mohan, 2011). Our recent work provides important new evidence that the availability of neurosteroids does indeed critically influence the propensity for seizures (Reddy and Zeng, 2007). We used epileptic female rats that had experienced SE. Spontaneous seizure activity was monitored for up to 5 months. The epileptic animals exhibited about two seizures per day, each lasting approximately a minute. Gonadotropin induced increase in neurosteroids was associated with reduced seizure intensity. However, when neurosteroids were withdrawn by using the neurosteroid synthesis inhibitor finasteride, a significant (two-fold) increase in seizure frequency was observed (Reddy, 2009a). These findings are confirmed in a recent study that utilized ovariectomized epileptic animals (Lawrence et al., 2010).

**CATAMENIAL EPILEPSY**

Catamenial epilepsy, the cyclical occurrence of seizure exacerbations during particular phases of the menstrual cycle in women with preexisting epilepsy, is a specific form of pharmacoresistant epilepsy. There are about 1.5 million women of child-bearing age with epilepsy in the United States; catamenial seizure exacerbations affect up to 70% of these women (Herzog et al., 2004; Bazan et al., 2005; Quigg et al., 2009; Reddy, 2009a; Kim et al., 2010; Verrott et al., 2010). Although there are several forms of catamenial epilepsy, neurosteroids have been implicated only in the seizure exacerbations that occur in the most common situation, which is when women with normal menstrual cycles experience seizure exacerbations in the perimenstrual period. It is hypothesized that withdrawal of progesterone-derived neurosteroids leads to enhanced brain excitability predisposing to seizures. During the menstrual cycle, circulating progesterone levels are low in the follicular phase but rise in the mid-luteal phase for about 10–11 days, before declining in the late luteal phase. Circulating allopregnanolone levels parallel those of its parent progesterone (Tuveri et al., 2008). In addition to neurosteroid fluctuations, plasticity in GABA-A receptor subunits could play a role in the enhanced seizure susceptibility in perimenstrual catamenial epilepsy. Animal studies have shown that prolonged exposure to allopregnanolone followed by withdrawal such as that occurs during menstruation causes a marked increase in expression of the α4-subunit, a key subunit linked to enhanced neuronal excitability, seizure susceptibility, and benzodiazepine resistance (Gulinek et al., 2001; Maguire et al., 2005; Shen et al., 2005; Smith and Gong, 2005; Smith et al., 2007; Gangisetty and Reddy, 2010). Although α4 can coassemble with γ2 to form synaptic GABA-A receptors, it preferentially coassembles with δ to form extrasynaptic GABA-A receptors. Overall, these neuroendocrine changes can result in reduced inhibition resulting in enhanced excitability, which, among other effects, predisposes to catamenial seizures.

We have developed a rodent model of perimenstrual cataminal epilepsy (Reddy et al., 2001; Reddy and Zeng, 2007). Rodents have a 4- to 5-day estrous cycle and studies of fluctuations in seizure susceptibility in cycling female rodents have not led to results that are relevant to the human menstrual cycle. In order to provide a model that more closely mimics the human situation, a condition of elevated progesterone was created in rats by gonadotropin treatment. This resulted in prolonged high circulating levels of estrogen and progesterone similar to those that occur in the luteal phase of the menstrual cycle. Then, to simulate the withdrawal of allopregnanolone that occurs at the time of menstruation, the animals were treated with finasteride 11 days after the initiation of gonadotropin treatment. Withdrawal of neurosteroids had led to decreased seizure threshold and increased seizure activity (Reddy et al., 2001). We have conducted additional studies using this paradigm in female rats with spontaneous recurrent seizures (Reddy and Zeng, 2007). In epileptic animals, neurosteroid withdrawal was associated with a marked increase in seizure frequency. In women with epilepsy, finasteride therapy had led to an increase in seizure frequency and severity (Herzog and Frye,
The neurosteroid allopregnanolone is involved in the pathophysiology of catamenial epilepsy. It is suggested that seizure susceptibility decreases when neurosteroid levels are high (mid-luteal phase), and increases during their withdrawal (perimenstrual periods) in close association with specific changes in GABA-A receptor subunits expression in the hippocampus. This premise has been investigated using a mouse hippocampus kindling model of catamenial epilepsy. Our results show that fully kindled mice undergoing neurosteroid withdrawal have increased generalized seizure frequency and intensity; enhanced seizure susceptibility; and, similar to the clinical catamenial seizure phenotype, reduced benzodiazepine-sensitivity, and enhanced neurosteroid potency (Gangisetty and Reddy, 2010; Reddy and Gould, 2011). The increased susceptibility to seizures and alterations in anti-seizure drug responses are associated with increased abundance of the δ and α4-subunits of GABA-A receptors in the hippocampus. However, the molecular mechanisms underlying the upregulation of α4-subunit expression remain unclear. The role of PRs and the transcription factor early growth response factor-3 (Egr3) in regulation of the GABA-A receptor α4-subunit expression in the hippocampus was investigated in a mouse neurosteroid withdrawal paradigm (Gangisetty and Reddy, 2010). Neurosteroid withdrawal-induced a threefold increase in α4-subunit expression in WT mice, but this upregulation was undiminished in PR knockout mice. The expression of the transcription factor early growth response factor-3 (Egr3), which controls α4-subunit transcription, was increased significantly following neurosteroid withdrawal in WT and PR knockout mice. Neurosteroid withdrawal-induced α4-subunit upregulation was completely suppressed by antisense Egr3 inhibition. These results support that neurosteroid withdrawal-induced upregulation of GABA-A receptor α4-subunit expression is mediated by the Egr3 via a PR-independent signaling pathway.

The neurosteroid withdrawal model of catamenial epilepsy was used to investigate therapies for perimenstrual catamenial epilepsy (Reddy and Rogawski, 2000b, 2001). A key result is that conventional antiepileptic drugs, including benzodiazepines and valproate, are less potent in protecting against seizures during the period of enhanced seizure susceptibility following neurosteroid withdrawal. This pharmacoresistance appears to mimic the situation in women with catamenial epilepsy where breakthrough seizures occur despite treatment with antiepileptic drugs. In contrast to the results with conventional antiepileptic drugs, neurosteroids, including allopregnanolone, THDOC, and their δβ-isomers, were found to have enhanced activity in the catamenial epilepsy model (Reddy and Rogawski, 2001). This suggested a “neurosteroid replacement” approach to treat catamenial seizure exacerbations (Reddy and Rogawski, 2009). A neurosteroid could be administered in a “pulse” prior to menstruation and then withdrawn, or continuously administered throughout the month. The neurosteroid would be administered at low doses to avoid sedative side effects. Such low doses are expected to contribute little anticonvulsant activity during most of the menstrual cycle. Patients would still require treatment with conventional antiepileptic medications. However, during the period of enhanced seizure susceptibility at the time of menstruation, the increased potency of the neurosteroid would confer protection against perimenstrual seizure exacerbations. It is noteworthy that while the anticonvulsant activity of neurosteroids increases in conjunction with neurosteroid withdrawal, there is no corresponding increase in side effects (Reddy and Rogawski, 2009). Therefore, side effects would not be expected to be enhanced negating the potential of the therapeutic approach.

Although neurosteroids seem to be the most direct approach to the treatment of catamenial epilepsy, there is only limited anecdotal data is available to support their use (McAuley et al., 2001). No neurosteroid is currently approved by the United States Food and Drug Administration (FDA). In contrast, two open-label trials have shown that adjunctive progesterone therapy produces significant reductions in seizure occurrence (Herzog, 2009). It is recommended that the hormone be administered during the entire second half of the menstrual cycle and tapered gradually as it is believed that abrupt discontinuation can result in rebound seizure exacerbation. Synthetic analogs of neurosteroids may overcome certain obstacles and side effects associated with natural progesterone therapy (see below, Neurosteroid Therapy section). Other therapeutic approaches may also be helpful for managing catamenial seizures (Vilos et al., 2011).

STRESS–SENSITIVE SEIZURE CONDITIONS

Neurosteroids are released during physiological stress. Stress results in the hypothalamic release of corticotropin-releasing hormone, which liberates ACTH from the anterior pituitary. Along with cortisol, ACTH also enhances the synthesis of adrenal deoxycorticosterone (Tan and Mulrow, 1975; Kater et al., 1989), which is released into the circulation and can serve as a precursor for synthesis of the neurosteroid THDOC (Figure 1). In contrast to allopregnanolone, which is present in the brain even after adrenalectomy and gonadectomy, THDOC appears to be derived nearly exclusively from adrenal sources (Purdy et al., 1990; Reddy, 2003). Plasma and brain levels of THDOC and allopregnanolone rise rapidly following acute stress (Purdy et al., 1991; Concasa et al., 1998; Reddy and Rogawski, 2002). Acute stressors such as swimming, foot shock or carbon dioxide exposure elicit an increase in allopregnanolone and THDOC concentrations in plasma and in brain (Barbaccia et al., 1996, 1997; Vallee et al., 2000).

Stress-induced neurosteroids have been demonstrated to elevate seizure threshold (Reddy and Rogawski, 2002). Stress-induced seizure protection could be due to circulating neurosteroids synthesized in peripheral tissues or to those produced locally in the brain. However, the effect of swim stress-induced increases in seizure threshold and THDOC levels in rats were abolished in adrenalectomized animals, implicating adrenal-derived THDOC. Despite stress-induced seizure protection in animals, patients, and clinicians are not likely to recognize a reduction in seizure frequency associated with stress. Indeed, stress has been reported to trigger seizure activity in persons with epilepsy (Temkin and Davis, 1984; Frucht et al., 2000). During stressful episodes adrenal hormone levels are expected to fluctuate and it may simply be the withdrawal of THDOC during such fluctuations that is associated with seizure provocation. Alternatively, other unidentified hormonal factors with proconvulsant activity may be responsible for stress-induced increases in seizures. However, chronic stress of...
the type experienced by patients with epilepsy likely has different endocrinological consequences than acute stress. The effects on seizures of fluctuations in neurosteroids in chronic stress remain to be studied.

TEMPORAL LOBE EPILEPSY
Neurosteroids may play a role in limbic epilepsy. Sexual and reproductive dysfunction are common among persons with epilepsy (Edwards et al., 2000). In particular, men with TLE often have diminished libido and sexual potency that is associated with low testosterone levels (Herzog et al., 1986; Brunet et al., 1995; Herzog, 2002). This hypogonadal state has been attributed to the effects of certain hepatic enzyme-inducing antiepileptic drugs, or alternatively – given the extensive connections between temporal lobe structures such as the amygdala and hypothalamic nuclei that govern the production and secretion of gonadotropin releasing hormone – to suppression of the hypothalamic–pituitary–gonadal axis by limbic seizures. There is evidence that serum androgens normalize after temporal lobe surgery which results in successful seizure control but not in those that continue to have seizures. This supports the view that seizures are responsible for the hypoandrogenic state (Bauer et al., 2000). Testosterone, as noted previously, is a precursor for at least three neurosteroids with anticonvulsant properties: 5α-androstanediol, androsterone, and etiocholanolone (Reddy, 2004a,b; Kaminski et al., 2005; Reddy and Jian, 2010). There is evidence that serum levels of at least two of these steroids (androsterone and etiocholanolone) are reduced in men with epilepsy compared with control subjects (Brunet et al., 1995). It is conceivable that reduced levels of such anticonvulsant neurosteroids leads to enhanced propensity for seizures and thus neurosteroid replacement might be a useful therapeutic approach.

Certain biological factors in TLE may influence the sensitivities of endogenous neurosteroids and could have an impact on the efficacy of exogenous neurosteroids used in epilepsy therapy. Studies in a SE model of TLE have shown a striking reduction in δ-subunit-containing GABA-A receptors in the dentate gyrus (Peng et al., 2004; Zhang et al., 2007), suggesting that neurosteroid effects on non-synaptic GABA-A receptors may be reduced. In addition, in dentate gyrus granule cells neurosteroid modulation of synaptic currents is diminished and α4-subunit-containing receptors are present at synapses (Sun et al., 2007). All of these changes may exacerbate seizures in epileptic animals but may reduce the efficacy of endogenous neurosteroids. The expression of neurosteroidogenic enzymes such as P450scc and 3α-HSOR appears to be elevated in the hippocampus in animals and human subjects affected by TLE (Stoffel-Wagner et al., 2000, 2003; Biagini et al., 2009). If local neurosteroidogenesis is enhanced, this may in part counteract the epileptogenesis-induced changes.

ALCOHOL-WITHDRAWAL SEIZURES
Alcohol withdrawal is known to be associated with seizures. Systemic administration of moderate doses (1–2.5 g/kg) of ethanol causes increases in plasma and brain neurosteroids that may contribute to many of the behavioral effects of ethanol in rodents (Morrow et al., 2006). This effect of ethanol is believed to be due to activation of the hypothalamic–pituitary–adrenal axis. As is the case in the catamenial epilepsy model, chronic ethanol-induced elevations in neurosteroids lead to an enhancement in the anticonvulsant actions of the neurosteroids allopregnanolone and THDOC (Devaud et al., 1996). These effects are associated with increases in the sensitivity of GABA-A receptors to neurosteroids (Morrow et al., 2006). Endogenous neurosteroids may protect against ethanol withdrawal seizures. However, ethanol induction of allopregnanolone is diminished in tolerant and dependent animals. Reduced availability of allopregnanolone under such circumstances may be a factor that predisposes to alcohol-withdrawal seizures. As is the case with catamenial epilepsy, neurosteroid replacement could conceivably be useful in the treatment of alcohol-withdrawal seizures, given that current pharmacological approaches are not entirely satisfactory.

STATUS EPILEPTICUS
Novel therapies are desperately needed for refractory SE, an emergency neurological condition characterized by persistent seizures lasting more than 30 min, progressive internalization of synaptic GABA-A receptors, and benzodiazepine resistance. The extrasynaptic δ-subunit-containing GABA-A receptors that generate “tonic” inhibition do not internalize during SE, so that neurosteroids, which are positive modulators of extrasynaptic and synaptic GABA-A receptors with robust anticonvulsant activity, could be more effective treatments for SE. Neurosteroids have been tested in animal models of SE (Kokate et al., 1996; Reddy, 2009b). Our recent studies indicate that THDOC therapy can effectively terminate electrographic and behavioral SE induced chemically by lithium-pilocarpine in rats (Kuruba and Reddy, 2011). We found that with early and late administration after SE onset, THDOC successfully aborted seizures with sustained suppression of SE, a profile superior to the benzodiazepine diazepam. In addition, THDOC therapy may confer significant neuroprotection by diminishing the neuronal cell death associated with SE. Further studies are needed to clarify whether neurosteroids might be valuable in the treatment of SE.

NEUROSTEROID THERAPY OF EPILEPSY
Despite intense research on neurosteroids, there is no neurosteroid-based drug available for patients. Ganaxolone, the synthetic 3β-methyl derivative of allopregnanolone, is the only neurosteroid that has been evaluated for the treatment of epilepsy in humans (Monaghan et al., 1999; Carter et al., 1997). Unlike allopregnanolone and related natural neurosteroids that can undergo back conversion by 3α-HSOR isoenzymes to hormonally active intermediates, the 3β-methyl substituent of ganaxolone eliminates such metabolism and thereby avoids hormonal side effects. Ganaxolone has similar pharmacological properties to the natural neurosteroids such as allopregnanolone (Reddy and Woodward, 2004). It has protective activity in diverse rodent seizure models, including clonic seizures induced by the chemoconvulsants pentylenetetrazol, bicuculline, flurothyl, aminophylline; limbic seizures in the 6-Hz model; amygdala and cocaine-kindled seizures; and corneal kindled seizures (Gasior et al., 2000; Lipiţăková et al., 2000; Reddy and Rogawski, 2000a, 2010b; Kaminski et al., 2003, 2004). During prolonged daily treatment, tolerance does not develop with the anticonvulsant activity of ganaxolone
A third study was an open-label non-randomized, dose-escalation study in female amygdala kindled mice, ganaxolone elicited strong efficacy in the treatment of epilepsy (Reddy and Woodward, 2004; Reddy and Rogawski, 2000a). Ganaxolone treatment was associated with significant reduction in the afterdischarge duration. As expected, there was a substantial suppression of behavioral and electrographic seizures in mice treated with clonazepam. While clonazepam was more potent than ganaxolone, the overall maximal efficacy of both drugs was similar. These studies provide strong evidence that the synthetic neurosteroid analog ganaxolone is highly effective antiseizure agent in the amygdala kindling model, which is a clinically relevant model of complex partial epilepsy.

CLINICAL STUDIES
Ganaxolone has been tested in various clinical trials to assess efficacy in the treatment of epilepsy (Reddy and Woodward, 2004; Rogawski et al., 2010). More than 900 subjects have received the drug at doses up to 1875 mg/day in adults and up to 54 mg/kg/day in children in phase 1 normal volunteer studies, epilepsy trials, and also clinical trials for migraine. Overall, the drug is safe and well tolerated. The most common side effect is reversible dose-dependent sedation. One epilepsy trial used the inpatient presurgical study design in adults with partial seizures (Laxer et al., 2000). A second study was an open-label, add-on trial in pediatric patients with a history of infantile spasms (Kerrigan et al., 2000). A third study was an open-label non-randomized, dose-escalation add-on trial in highly refractory pediatric and adolescent patients; three patients in this latter study were followed in an extension phase over 3.5 years (Pieribone et al., 2007). As discussed previously, there is limited anecdotal information supporting the efficacy of ganaxolone in the treatment of catamenial seizure exacerbations (McAuley et al., 2001). Recently, a double-blind, randomized, placebo controlled study was completed in adults with partial seizures (Rogawski et al., 2010). A separate trial was completed in children with infantile spasms. In this study, there was no clear statistically significant treatment effect although some subjects did appear to demonstrate a treatment-related reduction in spasm clusters. The adult trial included 147 subjects with partial onset seizures with or without secondary generalization who were refractory to conventional antiepileptic drugs. Ganaxolone treatment produced an 18% decrease in mean weekly seizure frequency, compared with a 2% increase for placebo over the 10-week treatment period. Results from the open-label extension phase of the study indicated that ganaxolone maintains its efficacy over time.

ADVANTAGES OF NEUROSTEROID THERAPY
An ideal new drug for epilepsy should have a rapid or intermediate onset of action that is effective against a broad range of convulsive and con-convulsive seizures. It should also be effective in SE even when given late after seizure onset, should exhibit no tolerance, exhibit no pharmacokinetic or teratogenic effects, be relatively safe, and readily available for clinical development. Neurosteroids partly meet or exceed these expectations, and possess several advantages: (i) Neurosteroids can be effective for broad seizure types, even in diazepam-refractory seizures because they can activate most GABA-A receptor isoforms; (ii) Unlike benzodiazepines, neurosteroids lack tolerance upon repeated or chronic treatment which has been proven in clinical trials; (iii) They show a rapid onset and intermediate duration of action; (iv) Well established mechanism of action at GABA-A receptors; (v) Maximal efficacy is expected even in resistant seizures, due to their positive and direct (non-allosteric) actions in promoting GABAergic inhibition at high dosage (vi); They promote tonic inhibition that does not rely on interneurons that may be damaged in some patients with TLE; and (vii) They are under clinical trials for epilepsy indications.

CONCLUSION
Neurosteroids that enhance the GABAergic neurotransmission are potent anticonvulsants and may regulate various neuronal excitability networks. Neurosteroids are believed to play a role in the regulation of seizure susceptibility in the setting of preexisting epilepsy. Menstrual and stress related fluctuations in seizures may be related to alterations in brain neurosteroids. Additionally, men with TLE who have a suppressed hypothalamic–pituitary–gonadal axis may have a reduction in testosterone-derived neurosteroids that could worsen seizures. New information on the role of neurosteroids in limbic epileptogenesis is emerging. Treatment with synthetic neurosteroids may be beneficial to patients with partial seizures. Further studies are required to determine whether “neurosteroid replacement” is a useful approach for epileptic seizures related to endogenous neurosteroid fluctuations, such as in catamenial epilepsy and stress. Novel agents that increase the brain synthesis of neurosteroids, such as TSPO ligands, may find utility in the treatment of epilepsy.
