METHODS
This is a single-center comparative analysis performed between April 1986 and May 2016. Two hundred and twelve liver transplantation (LT) were performed with donors ≥ 70 years old (study group). Then, we selected the first cases that were performed with donors < 70 years old immediately after the ones that were performed with donors ≥ 70 years old (control group).

RESULTS
Graft and patient survivals were similar between both groups without increasing the risk of complications, especially primary non-function, vascular complications and biliary complications. We identified 5 risk factors as independent predictors of graft survival: recipient hepatitis C virus (HCV)-positivity [hazard ratio (HR) = 2.35; 95% confidence interval (CI): 1.55-3.56; P = 0.00]; recipient age (HR = 1.04; 95%CI: 1.02-1.06; P = 0.00); donor age X model for end-stage liver disease (D-MELD) (HR = 1.00; 95%CI: 1.00-1.00; P = 0.00); donor value of serum alanine transaminase (HR = 1.00; 95%CI: 1.00-1.00; P = 0.00); and donor value of serum sodium (HR = 0.96; 95%CI: 0.94-0.99; P = 0.00). After combining D-MELD and recipient age we obtained a new scoring system that we called DR-MELD (donor age X recipient age X MELD). Graft survival significantly decreased in patients with a DR-MELD score ≥ 75000, especially in HCV patients (77% vs 63% at 5 years in HCV-negative patients, P = 0.00; and 61% vs 25% at 5 years in HCV-positive patients; P = 0.00).

CONCLUSION
A DR-MELD ≥ 75000 must be avoided in order to obtain the best results in LT with donors ≥ 70 years old.

Key words: Liver transplantation; Aged donors; Old donors; Marginal donors; Donor age

Core tip: The use of aged grafts is one of the main strategies to increase the number of available grafts. After analyzing the results of liver transplantation performed with donors ≥ 70 years old, we identified as independent predictors of graft survival: donor age X model for end-stage liver disease (D-MELD), recipient age and hepatitis C virus (HCV) infection. After combining D-MELD and recipient age we obtained a new scoring system that we called DR-MELD (donor age X recipient age X MELD), which seems to be a good measure to predict graft survival when using grafts ≥ 70 years old, regardless of the HCV infection.

INTRODUCTION
The increase of indications for liver transplantation (LT) and the shortage of liver donors has been one of the main problems for performing LTs in the past years[1-8]. The use of aged donors is one of the main strategies to increase the number of available grafts. Spain is the country with the highest donation rate per million population (pmp) worldwide[9]. Several studies comparing Spain and the United States showed that in Spain between 1999 and 2009 there was an increase in the donation rate by the population ≥ 70 years old from 3.8 donors pmp to 8.8 donors pmp (132% increase), while in the United States this rate only increased from 1 donor pmp to 1.3 donor pmp[10,11]. Spain represents one of the countries with the most experience using aged liver grafts.

There have been multiple studies analyzing the impact of donor age on LT results since Emre et al[12] published in 1996 the first long series of LTs with donors ≥ 70 years old. Initially the results were disappointing, but as the number of LTs performed with such grafts increased, the results progressively improved until becoming comparable to those obtained with younger grafts[12-22].

The aim of the present study is to identify predictors of graft survival with the use of donors ≥ 70 years old, and formulate a score able to predict graft survival in an attempt to develop a tool for daily donor-recipient matching.

MATERIALS AND METHODS
Data source and study population
This is a single-center comparative, longitudinal and retrospective analysis of all LTs performed at the “12 de Octubre” University Hospital of Madrid between April 1986 and May 2016. During this period 1848 LTs were performed in 1659 patients. Of these, 232 (12.6%) were performed with grafts from donors ≥ 70 years old. Recipients < 18 years old, retransplantation, acute liver failure, human immunodeficiency virus (HIV) positivity, combined transplants, split grafts, in-vivo donation, non-heart-beating donation, LTs due to metastatic liver disease and LTs with incomplete medical records were excluded from the analysis. Thus, 212 cases (study group) were included in the study (Figure 1). To minimize the impact of the era when the LT was performed, we selected as controls the first cases that were performed with a graft < 70 years old immediately after the ones that were performed with a graft > 70.
All LT recipients were evaluated before transplant in our department. The indication for LT was established according to our own policy and according to the ONT guidelines. The follow-up of each patient after the transplant was carried out based on the different protocols existing in our department.

The degree of hepatic insufficiency was evaluated with the Child-Pugh classification until 2003, and after that with the model for end-stage liver disease (MELD) score[23]. Refractory encephalopathy or ascites, hepatopulmonary syndrome, portopulmonary hypertension, refractory pruritus, recurrent cholangitis in patients with cholestatic liver disease, hereditary hemorrhagic teleangectasia, polycystic disease, multiple hemangiomatosis and hepatocellular carcinoma (HCC) were considered exceptions to MELD.

**Immunosuppressive regimen**

In all cases, an initial immunosuppressive (IMS) regimen based on the administration of a calcineurin inhibitor (tacrolimus or cyclosporine) and steroids was used. Other drugs (azathioprine, mycophenolate or mTOR inhibitors) were added in an individualized way depending on the clinical situation. Steroids were usually discontinued between 3 and 12 mo after LT in the cyclosporine regimen, and after 3 mo in the tacrolimus regimen.

**Definitions**

Primary non-function (PNF) was defined as early failure of liver function manifested by signs of acute liver failure: severe hypoglycemia, persistent coagulopathy, encephalopathy III-IV, acute renal failure, severe metabolic acidosis, hemodynamic instability and abnormal hepatic enzyme levels.

Acute rejection episodes were classified based on the Banff grades[24]. The initial treatment was based on the degree of rejection. Grade 1 rejections were treated by increasing the dose of IMS drugs, and grade 2 and 3 rejections were treated with 1 g of methylprednisolone intravenously for 3 d and steroid recycling. Corticosteroid-refractory rejections were treated with monoclonal antibodies: ATG and OKT3 in the initial period, and with thymoglobin and basiliximab thereafter.

Hepatitis C virus (HCV) recurrence in the graft was confirmed by histology based on the presence of periportal and lobular inflammation and the presence of fibrosis[25]. In our department, we do not have a biopsy follow-up protocol for HCV-patients undergoing LT, and therefore biopsies were only performed in the presence of elevated hepatic enzymes in the absence of abnormal vascular, biliary and IMS levels.

Vascular complications were defined as all post-transplant abnormalities in the hepatic artery, portal vein or cava vein requiring therapeutic procedures such as radiological or surgical procedures.

Biliary complications were defined as all post-

---

**Figure 1 Flowchart of the selection of the cases included in the present study.**

HIV: Human immunodeficiency virus.

1. All LT recipients were evaluated before transplant in our department. The indication for LT was established according to our own policy and according to the ONT guidelines. The follow-up of each patient after the transplant was carried out based on the different protocols existing in our department.

2. The degree of hepatic insufficiency was evaluated with the Child-Pugh classification until 2003, and after that with the model for end-stage liver disease (MELD) score[23]. Refractory encephalopathy or ascites, hepatopulmonary syndrome, portopulmonary hypertension, refractory pruritus, recurrent cholangitis in patients with cholestatic liver disease, hereditary hemorrhagic teleangectasia, polycystic disease, multiple hemangiomatosis and hepatocellular carcinoma (HCC) were considered exceptions to MELD.

3. In all cases, an initial immunosuppressive (IMS) regimen based on the administration of a calcineurin inhibitor (tacrolimus or cyclosporine) and steroids was used. Other drugs (azathioprine, mycophenolate or mTOR inhibitors) were added in an individualized way depending on the clinical situation. Steroids were usually discontinued between 3 and 12 mo after LT in the cyclosporine regimen, and after 3 mo in the tacrolimus regimen.

4. Primary non-function (PNF) was defined as early failure of liver function manifested by signs of acute liver failure: severe hypoglycemia, persistent coagulopathy, encephalopathy III-IV, acute renal failure, severe metabolic acidosis, hemodynamic instability and abnormal hepatic enzyme levels.

5. Acute rejection episodes were classified based on the Banff grades[24]. The initial treatment was based on the degree of rejection. Grade 1 rejections were treated by increasing the dose of IMS drugs, and grade 2 and 3 rejections were treated with 1 g of methylprednisolone intravenously for 3 d and steroid recycling. Corticosteroid-refractory rejections were treated with monoclonal antibodies: ATG and OKT3 in the initial period, and with thymoglobin and basiliximab thereafter.

6. Hepatitis C virus (HCV) recurrence in the graft was confirmed by histology based on the presence of periportal and lobular inflammation and the presence of fibrosis[25]. In our department, we do not have a biopsy follow-up protocol for HCV-patients undergoing LT, and therefore biopsies were only performed in the presence of elevated hepatic enzymes in the absence of abnormal vascular, biliary and IMS levels.

7. Vascular complications were defined as all post-transplant abnormalities in the hepatic artery, portal vein or cava vein requiring therapeutic procedures such as radiological or surgical procedures.

8. Biliary complications were defined as all post-
RESULTS

Donor characteristics
The donor characteristics are shown in Table 1. Aged donors were predominantly female whereas younger donors were predominantly male (P = 0.00). Obesity (27% vs 16%; P = 0.00), hypertension (58% vs 26%; P = 0.00) and diabetes (20% vs 7%; P = 0.00) were more common among aged donors. Although we found more cases of cerebrovascular deaths in the study group (81% vs 51%; P = 0.06), this difference was not statistically significant. Cardiac arrest was significantly lower in donors ≥ 70 years old (7% vs 25%; P = 0.00).

Median serum sodium level was high in both groups, but significantly lower in the study group. Median serum glutamic-pyruvic transaminase (GPT) and glutamic-oxaloacetic transaminase (GOT) levels were normal in both groups but, like sodium levels, they were significantly lower in aged donors. Biopsy findings were similar in both groups, with more than half of all cases without steatosis in each group.

Recipient characteristics
Table 2 lists recipient characteristics of the 2 groups. Mean recipient age was higher in recipients of older grafts. HCV-positivity was more common among patients undergoing LT with younger donors (34% vs 49%; P = 0.00). Median product of donor age and preoperative MELD (D-MELD) value was higher in the recipients of the study group (1051 vs 629; P = 0.00), but all laboratory parameters analyzed were similar in both groups.

Perioperative characteristics
Table 3 shows perioperative characteristics in the 2 groups. Mean cold ischemia time (CIT) was longer in the study group (445 min vs 386 min; P = 0.00). This is because most aged donors were from hospitals outside
of Madrid, and in some cases, it took up to 3 h for the grafts to reach our hospital. Transfusion requirements were similar in both groups and no differences were observed in the immunosuppressive treatment.

| Table 1  Donor characteristics n (%) |
|-------------------------------------|
| **Donors < 70 years old (n = 212)** | **Donors ≥ 70 years old (n = 212)** | **P value** |

| Home | 195 (92) | 197 (92.9) | |

HBV: Hepatitis B virus; HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma; MELD: Model for end-stage liver disease; D-MELD: The product of donor age and preoperative MELD; GOT: Glutamic-oxaloacetic transaminase; GPT: Glutamic-pyruvic transaminase; UNOS: United network for organ sharing; ICU: Intensive care unit.
Complications after LT

In Table 3 we can also observe the differences between the 2 groups regarding the development of different complications. Hospital stay in both intensive care unit (ICU) and conventional hospitalization unit were similar in both groups. No differences were found in relation to PNF, and acute rejection rate was similar in both groups (25% vs 29%; \( P = 0.39 \)). Infectious complications were lower in the study group, but differences were not statistically significant. The rate of vascular complications was similar in both groups (6.6% vs 5.2%; \( P = 0.80 \)). Although biliary complications were lower in the group of LTs performed with aged donors, differences were not statistically significant (5.2% vs 11.3%; \( P = 0.41 \)). Finally, HCV recurrence was similar in both groups, but severe HCV recurrence (F3-F4 hepatitis) was higher in the study group (50% vs 25%; \( P = 0.00 \)).

Survival analysis

After a mean follow-up of 67 ± 59 (range: 0-271) mo in the control group and a mean follow-up of 67 ± 61 (range: 0-269) mo in the study group, there were 67 (31.6%) deaths in the control group and 80 (37.7%) deaths in the study group. These differences were not statistically significant.

We also did not observe significant differences between the causes of death in each group, and the main causes in both groups were infections and medical complications.

Patient survival at 1, 3 and 5-years was 86.3%, 79.8% and 72.8%, respectively, in the control group and 83.8%, 78.1% and 69%, respectively, in the study group. Differences between the groups were not significant.

Graft survival at 1, 3 and 5-years was 85.3%, 78.4% and 70.2%, respectively, in the control group and 80.5%, 73.6% and 64.5%, respectively, in the study group. Again, differences between the groups were not significant.

Multivariate analysis

A Cox-regression analysis to investigate risk factors for graft loss in LTs performed with donors ≥ 70 years old was performed including all variables where we found differences during the comparative analysis and the ones that we considered clinically relevant. Table 4 shows the results. We identified 5 risk factors as independent predictors of graft survival: recipient HCV-positivity [hazard ratio (HR) = 2.35; 95% confidence interval (CI): 1.55-3.56; \( P = 0.00 \)]; recipient age (HR = 1.04; 95%CI: 1.02-1.06; \( P = 0.00 \)); D-MELD (HR = 1.00; 95%CI: 1.00-1.00); donor value of serum GPT (HR = 1.00; 95%CI: 1.00-1.00; \( P = 0.00 \)); and donor value of serum sodium (HR = 0.96; 95%CI: 0.94-0.99; \( P = 0.00 \)).

Graft survival according to risk factors

After combining D-MELD and recipient age we obtained a new scoring system that we called DR-MELD (product of donor age, recipient age and preoperative MELD). Median (interquartile range) DR-MELD in the study group was 58309 (27861). We stratified the recipients into 5 groups (DR-MELD < 25000; DR-MELD 25000-49999; DR-MELD 50000-74999; DR-

CIT: Cold ischemia time; WIT: Warm ischemia time; RBC: Red blood cells; FFP: Fresh frozen plasma; ICU: Intensive care unit.
MELD 75000-99999; and DR-MELD ≥ 100000), and we analyzed the graft survival according to this new score. Figure 3 shows the results. Overall, we obtained a graft survival of more than 70% at 5 years in patients with a DR-MELD score ≤ 75000, and of less than 50% in patients with a DR-MELD score ≥ 75000. Finally, we calculated graft survival according to DR-MELD and HCV infection status, and we observed that graft survival significantly decreased in patients with a DR-MELD score ≥ 75000, especially in HCV-positive patients (77% vs 63% at 5 years in HCV-negative patients, \(P = 0.00\); and 61% vs 25% at 5 years in HCV-positive patients; \(P = 0.00\)) (Figures 4 and 5).

**DISCUSSION**

Use of elderly donors is an effective mean to expand the donor pool with results similar to those described with the use of younger donors, as demonstrated in multiple studies over the past years\[12-22,26\]. In Europe, the use of these donors has become common. One single-center study reports that almost 40% of all LTs were performed with donors ≥ 70 years old\[26\]. However, in the United States, the use of these grafts is lower than in Europe, as shown in a recent study, where the rate of LTs performed with donors ≥ 70 years old in the United States was only 4.3% between January 2002 and September 2014\[27\].
According to the literature, and also as observed in the present study, elderly donors have a number of common characteristics. Females predominate over males. The rates of hypertension and diabetes are also higher among these donors. The main cause of donor death is the cerebrovascular accident, followed by trauma (81% vs 15%). Finally, there is a tendency to minimize other donor risk factors for a worse evolution. Thus, older donors have shorter ICU stays with fewer episodes of hemodynamic instability or cardiac arrest, and laboratory parameters such as serum sodium and transaminases are usually significantly lower.

In the literature, different factors have been described as predictors of graft survival, and most of them have been reported in several studies. A summary of predictors of graft survival with the use of donors ≥ 70 years old that were identified by multivariate analysis (Cox regression), is shown in Table 5. In our study, we identified 5 independent predictors of graft survival: donor serum sodium and serum GPT, recipient age, HCV, and D-MELD.

Sodium and GPT are laboratory parameters that in many studies have been identified as risk factors for a poor outcome, regardless of the age of the donor. However, in studies performed with donors ≥ 70 years old they never were found to be predictors of graft survival. In addition, although differences between these parameters were statistically significant in our study, we think that they are not clinically relevant since they were within the normal range in both groups.

HCV is a long-known survival predictor in LTs performed with aged donors. HCV recurrence is earlier and more aggressive when aged donors are used. In most of the studies performed with donors older than 70 years, we also observed that HCV was an independent predictor of graft survival. In recent years, younger grafts usually have been implanted in HCV-positive patients, while older livers were used to transplant patients with HCC and without HCV infection. Currently, with the arrival of direct-acting antivirals (DAA), the results of LT with aged donors in HCV patients have changed and donor age will not influence anymore LT results in HCV recipients.

It has been demonstrated that D-MELD is able to predict the results of LTs with donors older than 70 years, especially in HCV patients. Initially, Halldorson et al. proposed a D-MELD score of 1600 as a cut-off point to identify cases with significantly worse outcomes. In our study, these results were not confirmed when they were applied to recipients of grafts ≥ 70 years old, since we obtained a 5-year graft survival of 68.4% and 62.1% for D-MELD scores < 1600 and ≥ 1600, respectively (P > 0.05). We also did not obtain significant differences when we used different cut-off points proposed by other authors, or by applying still different ones. Although D-MELD was an independent predictor of graft survival in our study, we think that it should be used in combination with other parameters to improve its prediction power.

The age of the recipient is another parameter that in many studies has been linked with the result. In multiple series of LT with donors ≥ 70 years old, recipient age was an independent predictor of graft survival. Some authors proposed that these grafts should be limited to young recipients without other associated risk factors to obtain better results. However, in recent studies the mean age of the recipients was even higher in the group of transplants performed with elderly donors than in the group of...
transplants performed with younger donors.

In our study, other variables such as CIT, donor body mass index (BMI) and graft steatosis did not show a predictive value of graft survival (Table 4). However, we observed in the univariate analysis that the hazard ratio increased as the donor BMI and the steatosis percentage increased. Based on this observation and on an analysis of the results obtained by other authors\(^\text{[30,43]}\), we consider that the presence of steatosis ≥ 30% should be a contraindication for the use of these grafts. A graft biopsy should be mandatory to assess the presence of steatosis and it should always be done during the evaluation of an aged donor. More detailed studies are probably necessary to determine what percentage of steatosis should be the maximum recommended when using elderly grafts. Finally, CIT is a risk factor that has been related with a worse graft survival, and multiple studies recommend that it must be less than 8 hours when a graft ≥ 70 years old is used\(^\text{[8,26,30]}\). In our study, CIT was not an independent predictor of graft survival. This is probably because the mean CIT in the study group was 445 min, less than the 8 h recommended by most groups. We think, like other authors, that CIT should be as short as possible when aged grafts are going to be used, although a longer CIT should not be an absolute contraindication to use such grafts, and that this parameter must be analyzed case by case.

After analyzing the results of the multivariate analysis, we formulated a score using the D-MELD in combination with the age of the recipient (DR-MELD), and we analyzed its ability to predict graft survival in the study group according to the presence or absence of the HCV. We did not use serum donor GPT and sodium because, as we have previously seen, they were not clinically relevant. Overall, 5-year graft survival with donors ≥ 70 years old with a DR-MELD score < 75000 was 72%, while with a DR-MELD score ≥ 75000 it decreased to 53% (\(P = 0.00\)). Furthermore, with a DR-MELD score ≥ 75000, 5-year graft survival decreased significantly in HCV-negative patients (77% vs 63%, \(P = 0.00\)), but it decreased more significantly in HCV-positive patients (61% vs 25%, \(P = 0.00\)). Currently, with the effectiveness of the DAA, we can use an aged donor in a HCV-positive recipient with the same results than in a HCV-negative recipient. Given these results, DR-MELD seems to be a good measure to predict graft survival when using grafts ≥ 70 years old.

The present study is a single-center and longitudinal study, which ensures the homogeneity of the sample, the surgical technique and the follow-up. Furthermore, the fact that it is a single-center study and not based on a registry database has allowed the analysis of multiple variables of both donors and recipients. On the other hand, the study is retrospective and there is an important time difference between the first cases and the last ones; this may have a significant influence on the results, as other authors have noted\(^\text{[30]}\). Further studies are required to validate our results and compare them with other scores described in the literature, to define which of them is the most accurate.

GPT: Glutamic-pyruvic transaminase; Na: Serum sodium; BMI: Body mass index; UNOS: United network for organ sharing status; HCV: Hepatitis C virus; MELD: Model for end-stage liver disease; D-MELD: The product of donor age and preoperative MELD; BAR: Balance of risk score; CIT: Cold ischemia time.
In conclusion, the use of donors ≥ 70 years old is a safe strategy to expand the donor pool, and in the coming years they will probably become the main source of donation in western countries. Graft and patient survivals are similar to those obtained with the use of younger grafts without increasing the risk of complications, especially PNF, vascular complications and biliary complications. A DR-MELD ≥ 75000 must be avoided in order to obtain the best results. More studies are required to validate these findings.

ARTICLE HIGHLIGHTS

Research background
The increased life expectancy of the general population makes that donor age should also increase to ensure the number of available donors. Concerns regarding the use of aged organs are the perception of greater susceptibility to ischemic damage resulting in higher risk of initial poor function or primary non-function. There are limited published data evaluating results of liver transplantation (LT) with these donors and only a few of them try to identify predictors of graft survival.

Research motivation
Some authors have suggested that if we identify which variables are able to predict survival, careful donor to recipient matching could avoid some complications after LT with aged donors and improve patient and graft survival.

Research objectives
The main objective of our study is to evaluate LT outcomes with donors ≥ 70 years old using a large single-center cohort, identify predictors of graft survival and compare our results with previously published.

Research methods
We analyzed all LT performed at our department between April 1986 and May 2016 with donors ≥ 70 years old, then we compared the outcomes with those obtained using younger donors in the same period and finally a multivariate Cox proportional hazard model was applied to analyze the prognostic value for the risk of graft loss in all LT performed with aged donors.

Research results
The use of donors ≥ 70 years old is a safe strategy to expand the donor pool. Graft and patient survivals are similar to those obtained with the use of younger grafts without increasing the risk of complications, especially primary non-function, vascular complications and biliary complications. We identified 5 independent predictors of graft survival: donor serum sodium and serum glutamic-pyruvic transaminase, recipient age, hepatitis C virus (HCV) and donor age X model for end-stage liver disease (D-MELD). Finally, we formulated a score using the D-MELD in combination with the age of the recipient (we called it DR-MELD), and we analyzed its ability to predict graft survival in the study group according to the presence or absence of the HCV. A DR-MELD ≤ 75000 was a good measure to predict graft survival when using ≥ 70 years old regardless the presence of HCV.

Research conclusions
The use of aged donors in LT is not associated with higher primary non-function or other complications if we perform a careful donor selection. The current study emphasizes on the importance of identifying predictors of graft survival before donor to recipient matching. With the arrival of direct-acting antivirals, the results of LT with aged donors in HCV patients have changed and donor age will not influence anymore LT results in HCV recipients. Donor age, recipient age, MELD, cold ischemia time and the presence of steatosis seems to be the best predictors of graft survival after analyze the outcomes of several studies.

Research perspectives
The use of aged donors is a safe alternative to expand the donor pool in LT with brain death donors. Additional studies are needed to investigate if the donor age could also be increased with marginal donors such as non-heart beating, split or living donors.
