Abstract

Self-Attention has become prevalent in computer vision models. Inspired by fully connected Conditional Random Fields (CRFs), we decompose self-attention into local and context terms. They correspond to the unary and binary terms in CRF and are implemented by attention mechanisms with projection matrices. We observe that the unary terms only make small contributions to the outputs, and meanwhile standard CNNs that rely solely on the unary terms achieve great performances on a variety of tasks. Therefore, we propose Locally Enhanced Self-Attention (LESA), which enhances the unary term by incorporating it with convolutions, and utilizes a fusion module to dynamically couple the unary and binary operations. In our experiments, we replace the self-attention modules with LESA. The results on ImageNet and COCO show the superiority of LESA over convolution and self-attention baselines for the tasks of image recognition, object detection, and instance segmentation. The code is made publicly available.  

1. Introduction

Self-Attention has made a great influence in the computer vision community recently. It led to the emergence of fully attentional models [38, 51] and transformers [4, 17, 48]. Importantly, they show superior performances over traditional convolution neural networks on a variety of tasks including classification, object detection, segmentation, and image completion [31, 43, 49, 50].

Despite its remarkable achievement, the understanding of self-attention remains limited. One of its advantages is overcoming the limitation of spatial distances on dependency modelling. Originating from natural language processing, attention models the dependencies without regard to the distances among the words in the sequence, compared to LSTM [21] and gated RNN [13]. Being applied to vision models, attention aggregates the information globally among the pixels or patches [17, 51]. Similarly, compared to traditional convolutions, the features extracted by attention are no longer constrained by a local neighborhood.

We argue that global aggregations in self-attention also bring problems because the aggregated features cannot clearly distinguish local and contextual cues. We study this from the perspective of Conditional Random Fields (CRFs) and decompose it into local and context terms. The unary terms only make small contributions to the outputs, and meanwhile standard CNNs that rely solely on the unary terms achieve great performances on a variety of tasks. Therefore, we propose Locally Enhanced Self-Attention (LESA), which enhances the unary term by incorporating it with convolutions, and utilizes a fusion module to dynamically couple the unary and binary operations. In our experiments, we replace the self-attention modules with LESA. The results on ImageNet and COCO show the superiority of LESA over convolution and self-attention baselines for the tasks of image recognition, object detection, and instance segmentation. The code is made publicly available.

https://github.com/Chenglin-Yang/LESA
Figure 2. Effectiveness of LESA on COCO object detection and instance segmentation. For detection (first row), the existence of local terms enables LESA more capable of detecting objects in detail and correctly. For segmentation (second row), the combination of local and context terms makes LESA generate masks with higher semantic consistency.

*Figure 3*: Visual comparison of different mechanisms. LESA preserves objects’ structures and eliminates background artifacts. We illustrate this by comparing the LESA output to the output of standard convolution and self-attention. For each column, the first row shows the original image, the second row shows the convolution output, the third row shows the self-attention output, and the fourth row shows the LESA output.

The following text discusses the effectiveness of LESA on COCO object detection and instance segmentation. The figure compares the performance of LESA with traditional convolution and self-attention mechanisms. LESA is shown to improve the detection and segmentation accuracy, particularly in preserving object structures and reducing background artifacts.

In this paper, we enhance the unary term by incorporating it with convolutions and propose Locally Enhanced Self-Attention (LESA), which is visualized in Fig. 3. To analyze self-attention from the perspective of CRFs, let \( x \) be the input and \( x^{+1} \) the output of one layer of self-attention. Both of them are two-dimensional grid of nodes. At spatial location \((i, j)\), the node \( x^{+1}_{i,j} \) is connected to all the nodes \( x_{h,w} \) of the input. The binary term involves the computation on the edges \( x_{h\neq i,w\neq j} \rightarrow x^{+1}_{i,j} \) while the unary term the computation on the edge \( x_{h=i,w=j} \rightarrow x^{+1}_{i,j} \). Intuitively, these two terms indicate the activation by looking at itself (local) and the others (context). Through ablation study in Tab. 1, we find that the unary term is important for the performance but only contributing to the output less than 2% computed by the softmax operation in attention. Without the unary term, the feature extraction at \((i, j)\) entirely depends on interactions and loses the precise information of that pixel. The structure of the self-attention does not facilitate this unary operation. To address this issue, we enhance the unary term to \( x_{(h,w)\in N(i,j)} \rightarrow x^{+1}_{i,j} \) where \( N(i,j) \) indicate the pixels in neighborhood, and implement it as a grouped convolution followed by a projection layer.

To couple the unary and binary terms, we propose a dynamic fusion mechanism. The simplest static ways would be to assign equal weights to them or by setting their weights to hyper-parameters. By contrast, we enable the model to allocate the weights on demand. Specifically, for each layer \( l \) with the binary term, we multiply the binary term element-wisely by \( \omega_l(x) \in \mathbb{R}^{H\times W\times C} \). \( \omega \) depends on the input \( x \) and dynamically controls the weights of the binary terms to the unary terms for different layers \( l \), spatial locations \( H,W \), and feature channels \( C \).

We study the performance of LESA for image classification, object detection, and instance segmentation. We replace the spatial convolutions with LESAs in the last two stages of ResNet [19] and its larger variant WRN [58]. Then, we use them equipped with FPN [29] as the backbones in Mask-RCNN [18] to evaluate their performance for object detection and instance segmentation. The challenging large-scale datasets ILSVRC2012 [39] and COCO [30] are used to train and evaluate the models. The experiments demonstrate the superiority of LESA over the convolution and self-attention baselines.

To summarize, the main contributions of this work are:

- **Analyzing self-attention from the perspective of fully connected CRFs, we decompose it into a pair of local (unary) and context (binary) terms. We observe the unary terms make small contributions to the outputs. Inspired by the standard CNNs’ focus on the local cues, we propose to enhance the unary term by incorporating it with convolutions.**
• We propose a dynamic fusion module to couple the unary and binary terms adaptively. Their relative weights are adjusted as needed, depending on specific inputs, spatial locations, and feature channels.

• We implement Locally Enhanced Self-Attention (LESA) for vision tasks. Our experiments on the challenging datasets, ImageNet and COCO, demonstrate that the LESA is superior to the convolution and self-attention baselines. Especially for object detection and instance segmentation where local features are particularly important, LESA achieves significant improvements.

2. Related Work

2.1. Convolution

Convolutional Neural Networks (CNNs) have become the dominant models in computer vision in the last decade. AlexNet [27] shows considerable improvement over the models based on hand-crafted features [35, 40], and opens the door to the age of deep neural networks. Lots of efforts have been made to increase the width and depth and to improve the architecture and efficiency of CNNs in the pursuit of performance. They include the designs of VGG [42], GoogleNet [45], ResNet [19], WRN [58], ResNeXt [56], DenseNet [25], SENet [24], MobileNet [22], EfficientNet [46], etc. Through this process, the convolution layers are also being developed, leading to the grouped convolutions [56], depth-wise separable convolutions [11], deformable convolutions [14, 60], atrous convolutions [7, 33] and switchable atrous convolutions [9, 37].

2.2. Self-Attention

The impact of self-attention on vision community is becoming greater. Self-attention is originally proposed in approaches of natural machine translation [1]. It enables the encoder-decoder model to adaptively find the useful information according to contents from a variable length sentence. In computer vision, non-local neural networks [53] show that self-attention is an instantiation of non-local means [3], and use it to capture long-range dependencies to augment CNNs for tasks including video classification and object detection. A²-Net [10] employs a variant of non-local means and shows performance improvement on image classification. Recently, fully attentional methods [23, 38, 59] which replaces all the spatial convolutions with self-attention in the deep networks are proposed with stronger performances than CNNs. Axial attention [51] factorizes the 2D self-attention into two 1D consecutive self-attentions which reduces the computation complexity and enables the self-attention layer to have a global kernel. Self-attention also promotes the generation of transformers [4, 17, 31, 47, 48, 55]. BotNet [43] relates the transformer block with the fully attentional version of bottleneck block in ResNet [19].

2.3. Combining Self-Attention and Convolution

There are four categories of methods to combine the self-attention and convolution. Approaches in different categories can be used together.

The first one is using depth-wise convolution to replace the position embedding layer in self-attention, including CVPT [12] and CoaT [57]. The second one is the serial connection with convolution before attention. CvT [54] applies convolutions before calculating the query, key and value in self-attention. The third one is the serial connection with attention before convolution. Convolutions are applied after the self-attention layer, including LocalViT [28] and PVTv2 [52]. The final one is parallel connection. Attention Augmentation [2] augments the convolution features with attention features. It is intended to incorporate the long-range connections into the convolutions. Our approach, LESA falls into this category. Different from Attention Augmentation, it enhances the local term in self-attention.

3. LESA: Locally Enhanced Self Attention

3.1. Decomposition of Self-Attention

We decompose the self-attention into local and context terms. Let $x \in \mathbb{R}^{d_{in} \times H \times W}$ be the input, where $d_{in}$ is the feature channels and $H, W$ are the height and width in spatial dimensions. In this case, each pixel is connected with all the other pixels in the computation. We consider the all-to-all self-attention since it has been adopted as a building layer and shows superior performance [43, 51]. Specifically, we can write the formula of self-attention as:

$$x_{i,j}^{l+1} = \sum_{(h,w)=(1,1)} \text{softmax}(q_{i,j}^T h_{h,w} + q_{i,j}^T r_{(i,j)\rightarrow(h,w)}v_{h,w})$$

where $i,j$ and $h,w$ represent the spatial locations of the pixel and $l$ specifies the layer index. $q, k, v = xW_q, xW_k, xW_v$ are the query, key and value which are obtained by applying three different $1 \times 1$ convolutions on $x^l$. $W_q, W_k \in \mathbb{R}^{d_{in} \times d_{qk}}$ and $W_v \in \mathbb{R}^{d_{in} \times d_{out}}$ are learnable parameters, where $d_{qk}, d_{out}$ are intermediate and output channels. $r_{(i,j)\rightarrow(h,w)}$ is the relative position embedding, and for simplicity we will use the notation $r_{h,w}$. This formula shows the activation $x_{i,j}^{l+1}$ integrates the information conveyed by all the pixels $x_{i,j}$. To comprehend this operation, we decompose the information flow and reformulate the equation as the combination of local term and context
Figure 3. Visualizing Locally Enhanced Self-Attention (LESA) at one spatial location. The left part is the operation pipeline. $f_{map}$ is the feature map. The red and blue arrows represent the unary and binary operations.

The term:

$$x_{i,j}^{l+1} = S_{H,W}^{i,j}(q_{i,j}^T k_{i,j} + q_{i,j}^T r_{i,j}) v_{i,j} +$$

$$\sum_{(h,w)\neq (i,j)} S_{H,W}^{h,w}(q_{i,j}^T k_{h,w} + q_{i,j}^T r_{h,w}) v_{h,w}$$

(2)

For the spatial location $(i, j)$, the first local term computes activation by looking at itself, while the second context term computes activation by looking at others. The softmax generates the weights of contribution. Through this decomposition, we can interpret self-attention as a double-source feature extractor, which consists of a pair of unary and binary terms. Unary and binary terms are computed by the queries, keys, and values $q, k, v$ at different spatial locations with shared projection matrices $W_q, W_k, W_v$. Consequently, the outputs entangle the local and context features.

We perform an ablation study to investigate the contribution of these two terms. Specifically, we take a ResNet50 [19] and replace the convolution layers of its last two stages with self-attention. By tracking the softmax operations, we record the weights of the unary and binary terms $S_{H,W}^{h,w}$ and $\sum_{(h,w)\neq (i,j)} S_{H,W}^{h,w}$ in Equ. (2). They add up to 1 at each layer. The weight percentage is the average across all the layers. We observe that the unary term is important. The removal of unary terms whose weight percentage is less than 2% increases the error rate by 7.56% (or > 35% relative increase).

| Methods          | Top-1 Err. (%) | Weight Pct. (%) |
|------------------|---------------|-----------------|
| SA               | 21.31         | 100.00          |
| SA - unary term  | 28.87         | 98.03           |

Table 1. Contributions of the unary term in Self-Attention (SA). We replace the spatial convolutions in the 3rd and 4th stages of ResNet50 [19] with self-attention. By tracking the softmax operations, we record the weights of the unary and binary terms $S_{H,W}^{h,w}$ and $\sum_{(h,w)\neq (i,j)} S_{H,W}^{h,w}$ in Equ. (2). They add up to 1 at each layer. The weight percentage is the average across all the layers. We observe that the unary term is important. The removal of unary terms whose weight percentage is less than 2% increases the error rate by 7.56% (or > 35% relative increase).

We can observe that self-attention is mainly contributed by the binary operations, but the unary term is also important. Although the weights of unary terms only take less than 2%, the removal of which causes 7.56% drop of accuracy or 35% relative increase on the error rate. When analyzing the self-attention by this decomposition, unary term plays a significant role, but most of the computations and focuses are given to binary operations.

3.2. Locally Enhanced Self-Attention

Local and context terms have been long used in formulating the graphical models for vision tasks, such as image denoising, segmentation, and surface reconstruction [36]. The fully connected Conditional Random Fields (CRFs) have been introduced on top of the deep networks for semantic segmentation [8]. It aims at coupling the recognition
capacity and localization accuracy, and achieves excellent performance. For a grid of pixels in the form of a graph $G = (V, E)$, the energy to be minimized for the CRF is defined by:

$$
\phi_c = \sum_{x \in V} \Phi_U(x) + \sum_{(x_u, x_v) \in E} \Phi_B(x_u, x_v) (4)
$$

where $u, v$ indicate the different vertices in $V$. The unary term is $\Phi_U(x) = -\log(P(x))$ where $P(x)$ is the probability of assigning $x$ the ground truth label by the model. The binary term is $\Phi_B(x) = \pi((x_u, p_u), (x_v, p_v)) + \pi(p_u, p_v)$ where $x$ and $p$ are the contents and spatial positions. $\pi$ is the probability density function to measure the similarity of two values, which can be chosen as Gaussian.

The unary term is utilized for recognition while the binary term for spatial and content interactions. Inspired by these and our decomposition analysis, we propose Locally Enhanced Self-Attention (LESA). It contains a unary term incorporated with convolutions, and a binary term for feature interactions. Locally Enhanced Self-Attention is defined by

$$
x_{i,j}^{t+1} = m_{i,j} + \omega_{i,j} \sum_{(h,w) \in \{1,1\}} S_{H,W}^{h,w} q_{i,j}^h k_{h,w} v_{h,w} (5)
$$

$$
m = x W_g^k W_1^l \quad (6)
$$

where $\omega_{i,j}$ is the weight that is shown in Equ. (7). $m$ is the local term obtained by applying two consecutive convolutions. $W_g^k \in \mathbb{R}^{d_x \times d_{out}}$ is a learnable matrix where $k$ and $g$ represent the spatial extent and group number of the convolution. $W_1^l \in \mathbb{R}^{d_{out} \times d_{out}}$ is a learnable projection matrix representing $1 \times 1$ convolution. By this design, the multi-head mechanism is integrated. $m_{i,j}$ is the unary activation at spatial location $(i,j)$. This formulation of LESA also enables us to change $W_g^k$ to deformable convolution [14] for the tasks of object detection and instance segmentation. Self-attention focuses on the binary operations. We use it as the context term to model the feature interactions with relative spatial relationships among all possible pairs of pixels.

3.3. Dynamic Fusion of the Unary and Binary Terms

Adding the unary and binary terms is a static way of merging the two terms with equal weights. A more flexible strategy is to allocate the weights on demand under different circumstances. For example, in object detection, the locality of pixel dependencies is more important than the context when detecting multiple small objects in an image. We achieve a dynamic control by multiplying the binary term by $\omega$ and adaptively adjusting the relative weights of the two terms, which is shown in Equ. (5). Specifically, we can write the formula of $\omega_{i,j}$ as:

$$
\omega_{i,j} = \text{sigmoid}(F(m_{i,j} \parallel \sum_{(h,w) \in \{1,1\}} S_{H,W}^{h,w} q_{i,j}^h k_{h,w} v_{h,w})) (7)
$$

where $\omega \in \mathbb{R}^{d_{out} \times H \times W}$ and $\omega_{i,j}$ corresponds to one spatial location. $F : \mathbb{R}^{2d_{out} \times H \times W} \mapsto \mathbb{R}^{d_{out} \times H \times W}$ is a function. Sigmoid operation is performed element-wisely on the logits given by $F$, making $\omega$ range from 0 to 1. Regarding $F$, we design it as a three-layer perceptron and adopt the pre-activation design [20]. Concretely, together with sigmoid we can represent the pipeline as $F \rightarrow \text{sigmoid} : \text{BN} \rightarrow \text{relu} \rightarrow fc_1 \rightarrow \text{BN} \rightarrow \text{relu} \rightarrow fc_2 \rightarrow \text{BN} \rightarrow \text{sigmoid}$ where BN is batch normalization layer [26], and $f_{c1} : \mathbb{R}^{2d_{out}} \mapsto \mathbb{R}^{d_{out}}$, $fc_2 : \mathbb{R}^{d_{out}} \mapsto \mathbb{R}^{d_{out}}$ are two fully connected layers. The position embedding is omitted in Equ. 5 and 7 for simplicity. In our design, $\omega$ depends on the contents of the unary and binary terms and controls their relative weights at different spatial locations and in different feature channels.

4. Experiments

4.1. ImageNet Classification

- Settings We perform image classification experiments on ILSVRC2012 [39] which is a popular subset of the ImageNet database [15]. There are 1.3M images in the training

| Models | Ops. | Pms (M) | Acc.(%) | Weights (%) |
|--------|------|---------|---------|-------------|
|        |      |         | T-1     | T-5         | Unary | Binary |
| R50    | Conv. | 25.6    | 76.1    | 92.9        | 100   | 0      |
| R50    | SA    | 18.1    | 78.7    | 94.2        | 2.0   | 98.0   |
| R50    | LESA  | 23.8    | 79.6    | 94.8        | 67.0  | 33.0   |
| WR50   | Conv. | 68.9    | 78.5    | 94.1        | 100   | 0      |
| WR50   | SA    | 37.7    | 79.7    | 94.7        | 2.5   | 97.5   |
| WR50   | LESA  | 60.6    | 80.2    | 95.1        | 66.9  | 33.2   |
Table 3. COCO object detection and instance segmentation on val2017. We use Mask-RCNN [18] and HTC [5] frameworks and employ FPN [29] on the backbones ResNet [19] and WRN [58]. Conv. stands for deformable convolutions. We adopt two standard training schedules that have 12 and 20 epochs. The learning rate is adjusted 10 times smaller after 8, 11 epochs and 16, 19 epochs, respectively. The images are resized to $1024 \times 1024$ by default, and the superscript $^\text{b}$ (higher resolution) indicates that they are resized to $1280 \times 1280$. We can observe that LESA outperforms the convolution, self-attention, and deformable convolution baselines in all the experiments.

Table 4. COCO object detection and instance segmentation on test-dev2017 for the models in Tab. 3.

set and 50K images in the validation set. In total, it includes 1,000 object classes.

ResNet [19], a family of canonical models or backbones for vision tasks, and its larger variant WRN [58] are used to study LESA. There are 4 stages in ResNet and each one is formed by a series of bottleneck blocks. ResNet50 can be represented by the bottleneck numbers $\{3, 4, 6, 3\}$. We replace the conv3 $\times$ 3 in the bottleneck with the self-attention and LESA. The kernel channels of these conv3 $\times$ 3 in WRN are twice as large as those in ResNet.

We perform the replacement in the last two stages, which is enough to show the advantages of LESA. For convolution baselines, we use Torchvision official models [34]. For self-attention baselines and LESA, we set head number 8 for both of them and train the models from scratch. We set the stride of the last stage to be 1 following [43]. We keep the first bottleneck in stage 3 unchanged which has the stride 2 convolution. We employ a canonical training scheme with 5 linear warm-up and 90 training epochs with a batch size 128. Following [38, 51], we employ SGD with Nesterov momentum [32, 44] and cosine annealing learning rate initialized as 0.05. The experiments are performed on 4 NVIDIA TITAN XP graphics cards.

- **Results** The results are summarized in Tab. 2. For both the top-1 and top-5 accuracy, LESA surpasses the convolution and self-attention baselines. Our dynamic fusion module controls the binary term using $\omega$ in Equ. (7), and thus the weights for the unary and binary terms are $\frac{1}{1+\omega}$ and $\frac{\omega}{1+\omega}$, respectively. As $\omega$ is dependent on the inputs, spatial locations, and feature channels, we average the weights
across them in our records. In self-attention, the weights are calculated by softmax operations as used in Tab. 1. It is observed that the weight distribution in self-attention are imbalanced. The unary term only has a weight percentage less than 3\%, more than 32 times smaller than the binary term’s. While for LESA, their weight percentages are about 67\% and 33\%, respectively. In the tasks of object detection where local cues are particularly important, LESA shows better improvement, which is shown in Tab. 3 and 4.

4.2. COCO Object Detection and Instance Segmentation.

- **Settings** We perform object detection experiments on COCO dataset [30] and use the 2017 dataset splits. There are 118K images in the training set and 5K images in the validation set. In total there are 80 object categories and on average each image contains 3.5 categories and 7.7 instances.

  The widely used Mask-RCNN [18] and HTC [5] with the backbones equipped with FPN [29] are used to study LESA for object detection and instance segmentation. We use mmdetection [6] as the codebase. The ImageNet pre-trained checkpoints are utilized to initialize the backbones. There are 5 stages in the ResNet-FPN and the output strides are \{4, 8, 16, 32, 64\}. We replace the spatial convolutions in the 3rd and 4th stages. The images are resized to 1024 × 1024 and 1280 × 1280 in the experiments. Since the image size in classification is 224 × 224, we initialize new position embedding layers used in [38,41]. For training, we employ the 1× and 20e schedules. The total epochs and epochs after which the learning rate is multiplied by 0.1 are \{12, 8, 11\} and \{24, 16, 19\}, respectively. For the HTC framework, we employ multi-scale training for both the baseline and our method: with 0.5 probability that both sides of the image are resized to a scale uniformly chosen from 512 to 1024, and with another 0.5 probability to a scale that is uniformly sampled from 1024 to 2048. Mask-RCNN does not use multi-scale training.

  We also study adopting the deformable unary terms in LESA. Specifically, we replace \(W^k\) in Equ. (6) to deformable convolutions [14]. We set the group number of offsets as 1. Following the standard setting [37], the convolutions in the 2nd stage in both the baselines and our models are also replaced with deformable convolutions. Our experiments with Mask-RCNN framework are performed on 4 NVIDIA TITAN XP graphics cards and those with HTC framework on 4 TITAN RTX graphics cards.

- **Results** The results are summarized in Tab. 3 and 4. We use the same testing pipeline for val2017 and test-dev2017. LESA provides the best bounding box mAP and mask mAP for all the small, medium, and large objects compared with convolution, self-attention, and deformable convolution baselines in all scenarios.
## Methods

| Categories                          | Methods                  |
|------------------------------------|--------------------------|
| Conv. as position embedding of SA   | CVPT; CoaT               |
| Serial Conn. with Conv. before SA   | CvT:                     |
| Serial Conn. with Conv. after SA    | LocalViT; PVTv2          |
| **Parallel Conn.**                 | AA: static LESA; LESA    |

Table 5. Categories of merging methods for convolution and self-attention (discussed in the related work section). Conn. stands for connection. Approaches in different categories can be used together. As a parallel connection method, LESA is compared with AA (Attention Augmentation) in Tab. 6, and shows the superior performances.

Figure 5. Training and testing curves of ablation studies. AA stands for Attention Augmentation [2]. The right figure shows the details in the rectangular region of the left figure.

### 5. Relationships with other methods

- **Relationship with other enhanced self-attention methods** LESA is proposed as a combination mechanism for convolution and self-attention, which can be used with other enhanced self-attention together.

- **Relationships with other merging methods for self-attention and convolution** As summarized in Tab. 5 and discussed in related work section, there are four categories, and approaches in different ones can be use together. LESA falls into the category of parallel connection. We compare LESA with Attention Augmentation [2] and meanwhile, perform the ablation studies. Static LESA stands for adding the unary and binary terms of LESA without the dynamic fusion module.

The experiments are performed on ImageNet. The setting is the same as the main experiments. The results are summarized in Tab. 6. It is observed the performance difference between Attention Augmentation and self-attention is marginal. Both Static LESA and LESA show better performances than Attention Augmentation with less parameters. LESA has stronger performance than the static one, demonstrating effectiveness of the dynamic fusion module.

| Operations | Params (M) | Accuracy (%) |
|------------|------------|--------------|
|            | Top-1      | Top-5        |
| Convolution| 25.56      | 76.13        | 92.86 |
| Self-Attention | 18.06     | 78.69        | 94.22 |
| AA [2]     | 25.15      | 78.74        | 94.23 |
| Static LESA| 20.43      | 79.12        | 94.62 |
| LESA       | 23.78      | 79.55        | 94.79 |

Table 6. Parallel connection methods and ablation studies. The experiments are performed with ResNet50 [19] on ImageNet. The spatial convolution layers in last two stages are replaced. AA stands for Attention Augmentation [2], which is another parallel connection method of combining convolution and attention. Static LESA stands for adding the unary and binary terms without the dynamic fusion module. Both Static LESA and LESA achieve better performances than AA with less parameters. The effectiveness of the dynamic fusion module can be proved by the superiority of LESA over Static LESA.

### 6. Conclusion

From the perspective of fully connected Conditional Random Fields (CRFs), we decouple the self-attention into the local and context terms. They are the unary and binary terms that are calculated by the queries, keys and values in the attention mechanism. However, there lacks distinction between the local and context cues as they are obtained by using the same set of projection matrices. In addition, we observe the contribution of the local terms is very small which is controlled by the softmax operation. By contrast, the standard Convolutional Neural Networks (CNNs) show excellent performances in various vision tasks and rely solely on the local terms.

In this work, we propose Locally Enhanced Self-Attention (LESA). First, we enhance the unary term by incorporating it with convolutions. The multi-head mechanism is realized by using grouped convolution followed by the projection layer. Second, we propose a dynamic fusion module to combine the unary and binary terms with input-dependent relative weights. We demonstrate the superiority of LESA over the convolution and self-attention baselines in the tasks of ImageNet classification, and COCO object detection and instance segmentation.

**Limitations** LESA shares a common limitation with self-attention, which is the large memory consumption. This is due to the large dimensions of the similarity matrix which is computed by the queries and keys and where the softmax operation is applied. Our future works include designing a LESA that consumes small memory but still has the great power of capturing the context information. This will also address the common memory issue in other self-attention models.
