Vitamin D has been discovered centuries ago, and current studies have focused on the biological effects of vitamin D on adipogenesis. Besides its role in calcium homeostasis and energy metabolism, vitamin D is also involved in the regulation of development and process of metabolic disorders. Adipose tissue is a major storage depot of vitamin D. This review summarized studies on the relationship between vitamin D and adipogenesis and furthermore focuses on adipose metabolic disorders. We reviewed the biological roles and functionalities of vitamin D, the correlation between vitamin D and adipose tissue, the effect of vitamin D on adipogenesis, and adipose metabolic diseases. Vitamin D is associated with adipogenesis, and vitamin D supplements can reduce the burden caused by metabolic diseases. The review provides new insights and basis for medical therapy on adipose metabolic diseases.

1. Introduction

Vitamin D is an essential nutrient for the prevention of rickets and is responsible for the intestinal absorption of calcium, phosphate, and magnesium [1, 2]. Vitamin D can be obtained from food, but most of it is synthesized from 7-dehydrocholesterol in the skin via ultraviolet irradiation [3, 4]. The mechanism of vitamin D action is through its active form, 1α, 25-dihydroxyvitamin D3 [1α, 25(OH)2D3], which regulates the transcription of target genes and thus plays an important role in calcium homeostasis and metabolism [5–7]. Vitamin D deficiency or insufficiency is still a common issue in developing countries [8, 9]. Among 734 adolescents ranging from 12 to 18 years, 87.6% of participants had vitamin D deficiency [10]. Aside from its involvement in calcium and bone mineralization, vitamin D has multiple functions in adipose tissue, adipogenesis, glucose-insulin homeostasis, cell growth, and so on [11–13].

Adipose tissue is a vital organ in energy homeostasis and glucose metabolism [14–16]. Adipose tissue is also an endocrine organ secreting proteins and releasing fatty acids [17, 18]. It is composed of various cell types, including mature adipocytes, preadipocytes, fibroblasts, macrophages, and immune cells. The predominant cell types existing in adipose tissue are mature adipocytes. Preadipocytes differentiate into mature adipocytes in adipose tissue, and this process requires the regulation of transcription factors (peroxisome proliferator-activated receptor (PPAR), CCAAT enhancer-binding protein (C/EBP), and Kruppel-like factor proteins) [19, 20]. Vitamin D is mainly stored in adipose tissue, while vitamin D receptor (VDR) is expressed in adipose tissue [21, 22]. VDR is an activated transcription factor of active vitamin D. Previous studies investigated the effect of vitamin D on adipogenesis in animal models [23, 24], and results suggested that vitamin D exerts antiadipogenic activity in 3T3-L1 preadipocytes [25–27]. Meanwhile, vitamin D deficiency or insufficiency is involved in the regulation of insulin secretion, glucose levels, and inflammation causing adipose metabolic diseases, such as obesity, multiple sclerosis, diabetes, and fatty liver [28–32].

Hence, we reviewed the correlation between vitamin D and adipose tissue, along with related metabolic disorders.
(diabetes, nonalcohol fatty liver, and cardiovascular diseases). This study aimed to establish the relationship between vitamin D and metabolic disorders and furthermore to determine whether such disorders are affected by vitamin D supplementation, adipose vitamin D metabolism, and increased or reduced vitamin D activation. The vitamin D status, regulation of vitamin D by adipose tissue, effect of vitamin D on adipogenesis, and related metabolic diseases were also discussed.

2. Bioactivation of Vitamin D

Only a small amount of fat-soluble vitamin D can be obtained from the diet and from supplements [33]. The major source of vitamin D is produced in the skin through a sunlight-dependent chemical reaction [4, 34]. Exposure of the skin to ultraviolet-B radiation from the sun converts 7-dehydrocholesterol into previtamin D₃, which can be isomerized to vitamin D₃ [35]. Vitamin D₃ is then converted into calcifediol (25-(OH)D) in the liver and further hydroxylated into 1,25(OH)₂D in the kidney (Figure 1) [36]. Normally, the serum concentration of 25-(OH)D is measured to determine an individual’s vitamin D status in serum, whereas 1,25(OH)₂D is the biological active form of vitamin D [37–39].

The biological activity of 1,25(OH)₂D₃ is mediated through binding to VDR [40]. VDR is also well-documented as calcitriol receptor and is a member of the steroid hormone nuclear receptor family [41]. In humans, VDR is encoded by the VDR gene [42]. VDR widely exists in tissues and cells, such as skeleton, kidney, renal, skin, and immunocytes [4]. In nuclear, 1α,25-(OH)₂D₃, which is the active form of vitamin D, is capable of binding to VDR and form a heterodimer with retinoid X receptor (RXR); the complex binds to RNA polymerase and VDR interacting protein, resulting in the regulation of DNA transcription [43, 44]. Downstream targets of VDR are involved in calcium homeostasis, immune response, and cancer development [45]. Hindered VDR expression can impact diverse diseases, including cardiovascular disease, diabetes, tumors, tuberculosis, and multiple sclerosis [46].

After dietary intake, vitamin D needs to be absorbed by meal of fat through passive diffusion in the intestine. The absorbed vitamin D is transported to the liver by binding to diverse plasma proteins, such as vitamin D-binding protein (DBP), β-lipoprotein, and albumin [47–49]. DBP is an important carrier protein that can attenuate the toxicity of vitamin D by limiting its bound metabolites to target cells [50]. In the liver, vitamin D is converted into 25(OH)D catalyzed by the several hepatic cytochrome P-450s [51–53]. Of note, the metabolite is released into plasma and transported to the kidney, where it is converted into 1,25(OH)₂D, and is finally transported throughout the body (Figure 1) [54]. After synthesis, absorption, and transport, active vitamin D is distributed to hydrophobic parts of tissues [55]. Unlike other fat-soluble vitamin, vitamin D is not stored in the liver (except in some fish livers) [56]. Vitamin D is mostly stored in adipose tissue, and a large amount of vitamin D is combined with lipid, resulting in release and metabolic difficulties [57, 58].

3. Vitamin D and Lipid Metabolism

3.1. Regulation of Activation of Vitamin D by Adipose Tissue.

Aside from the important roles of vitamin D in intestinal calcium, phosphate uptake, and bone mass regulation, it is
also involved in other processes, including cell growth, immune functions, inflammation regulation, and neuromuscular functions [59–63]. Vitamin D could be regulated by hydroxylation that includes two-step enzymatic processes. Hydroxylation is performed by enzymes CYP27B1, CYP2J2, CYP27A1, and CYP3A4 in the liver and CYP27B1 in the kidney [64]. These enzymes are consecutively expressed in subcutaneous adipose tissue (SAT) and visceral adipose tissue [65, 66]. The CYP27B1 gene is expressed in the SAT of lean individuals and in 3T3-L1 preadipocytes, and it is regulated by calcitonin, hormones, calcium, and phosphorus [53]. Thus, the location of these enzymes in adipose tissue could implicate the production of active vitamin D.

Previous reports showed that the concentrations of vitamin D in blood below 50 nmol/L indicated vitamin D deficiency, and the reference values of vitamin D levels in blood should exceed 75 nmol/L; lower serum vitamin D levels correlated with higher frequency of obesity and excessive body weight [67–69]. Circulating 25(OH)D level depends on the storage of vitamin D in adipose tissue, indicating that adipose tissue probably affects the activation, regulation, or action of obesity via regulation of vitamin D [57, 70, 71]. In the presence of calcitriol, adipogenesis is blocked by VDR via downregulating both C/EBPβ nuclear protein levels and mRNA expression. In addition, 1,25(OH)2D3 allows for the upregulation of eight twenty-one (ETO), which is the core-repressor of C/EBPβ, and finally leads to C/EBPβ deficiency in adipogenesis [72]. VDR expression in 3T3-L1 cells inhibited PPARγ mRNA levels, which decreased adipogenesis [73]. These data indicated that VDR reduced adipogenesis through decreasing the expression of C/EBPβ and PPARγ and increasing ETO expression. The molecular mechanism of inhibitory effect of VDR on adipogenesis maybe due to the fact that RXR is a heterodimeric partner for both PPARγ and VDR, respectively, and that VDR leads to competition between RXR and PPARγ to decrease adipogenesis (Figure 2). Previous studies confirmed the competitive relationship between VDR and PPARγ for RXR [73–75]. Certainly, the mechanism underlying still needs to be proved by further investigation. Taken together, these investigations suggest that vitamin D plays a complex role through VDR and the transcription pathways in regulating adipogenesis.

3.2. Effect of Active Vitamin D on Adipogenesis. Adipogenesis is a cascade of differentiation that leads to adipocyte maturation. Adipocytes can affect many adipogenesis-related functions, such as adipokine secretion, lipid synthesis, fatty acid transfection, and insulin signaling response [76]. A vast amount of molecular interactions is involved during adipogenesis, and the main component is the expression of C/EBPβ and PPARγ [77]. C/EBPβ and C/EBPδ are expressed in the early stage of adipogenesis. The adipogenesis is promoted under the regulation of C/EBPα, β, and δ [78]. 1,25(OH)2D3 can inhibit 3T3-L1 preadipocyte
Vitamin D is associated with insulin resistance phenotype [119]. The causes of NAFLD are diabetes, obesity, age, and diet [120]. NAFLD has two types, namely, nonalcoholic fatty liver and nonalcoholic steatohepatitis [121, 122]. This disease is usually treated through weight loss and exercise. NAFLD is the most common chronic liver disorder in western countries [123]. It is a continuous process of liver injury, which may lead to steatohepatitis, cirrhosis, and liver cancer [124]. Vitamin D plays an important role in NAFLD development [125]. About 75% of 5847 insulin resistance and metabolic syndrome patients have vitamin D deficiency [126]. The serum concentration of 1,25(OH)D is lower in patients with NAFLD than in normal patients, and the fatty liver index is negatively correlated with 1,25(OH)D level [127]. Treatment with vitamin D can improve insulin resistance in patients with glucose intolerance [128]. In vivo studies found that vitamin D deficiency and VDR knockdown reduce the secretion of insulin from pancreatic β-cells [129]. These results support that low levels of serum 25(OH)D are related to NAFLD.

Vitamin D is associated with insulin resistance phenotypic markers, such as HOMA-IR, ISI, adiponectin, triglyceride, and high-density lipoprotein cholesterol [130, 131]. A prospective study on 524 nondiabetic patients
Aged 40–69 years has reported that serum 25(OH)D level is negatively correlated with blood glucose level and insulin resistance level [132]. The decrease in insulin sensitivity, pancreatic β-cell function, and insulin synthesis and secretion caused by low vitamin D level is related to insulin resistance. Vitamin D deficiency can promote the progress of impaired glucose tolerance, increase the expression of renin angiotensin system components, and damage the transcriptional function of pancreatic genes [133]. Vitamin D also decreases insulin resistance by downregulating the expression of PPARγ2, suppressing the differentiation of 3T3-L1 preadipocytes, and inhibiting adipogenesis [134]. Studies in vivo and in vitro showed that vitamin D is related to the pathogenesis and progress of NAFLD.

4.3. Cardiovascular Risk. Previous study indicated that endothelial dysfunction represents an early event in cardiovascular diseases, and there is an association between vitamin D levels and endothelial dysfunction. In addition, vitamin D levels negatively correlated with flow-mediated dilatation (FMD) in many patients affected by type 2 diabetes, whereas current data are still insufficient to confirm vitamin D deficiency or insufficiency lead to an increased cardiovascular risk [135]. The relationship between vitamin D deficiency and cardiovascular risk, as well as mechanism underlying also still needs to be proved by further investigation.

5. Conclusions

This review was dedicated to reveal the correlation between vitamin D and adipogenesis, with emphasis on the diseases related to adipose metabolic disorders. Vitamin D has several influences on adipogenesis. Active vitamin D is mainly produced, stored, and degraded in adipose tissue, and VDR is expressed in adipose tissue. Vitamin D affects adipogenesis by regulating the expression of adipocyte transcription factors, such as PPARγ, C/EBPα, and LPL, and through affecting insulin resistance, VDR and unliganded VDR, and adipokine secretion.

Adipose metabolic disorders, such as obesity, diabetes, and NAFLD, were specifically chosen in this review. Obesity is a common occurrence worldwide, and it can lead to diabetes and NAFLD. Many studies have indicated that vitamin D deficiency or insufficiency plays an important role in the development and process of obesity, diabetes, and NAFLD. Aside from the diseases discussed in the review, other diseases are also associated with vitamin deficiency, such as hyperlipidemia, ketosis, ketonuria, and atherosclerosis. However, the effect of vitamin D on adipogenesis in lean individuals and the function of calcium in adipogenesis are still keeping elusive. Vitamin D supplements are a promising way to alleviate the burden caused by these diseases. In conclusion, vitamin D administration can provide a new basis for medical therapy.

Conflicts of Interest

We declare that we have no conflicts of interest.

Authors’ Contributions

All authors participated in the search, writing, and revising of the manuscript. Zhiguo Miao and Shan Wang contributed equally to this work.
