We show that the measured yield ratio $^{3}_Λ$H/$^{3}_Λ$He in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV and in Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV can be understood within a covariant coalescence model if (anti)-Λ particles freeze out earlier than (anti)-nucleons but their relative freezeout time is closer at $\sqrt{s_{NN}} = 2.76$ TeV than at $\sqrt{s_{NN}} = 200$ GeV. The earlier (anti)-Λ freezeout can significantly enhance the yield of (anti)hypernucleus $^{3}_Λ$H ($^{3}_Λ$He), leading to that $^{3}_Λ$H has a comparable abundance with $^{3}_Λ$He and thus provides an easily measured antimatter candidate heavier than $^{3}_Λ$He.

The future measurement on $^{3}_Λ$H ($^{3}_Λ$He) would be very useful to understand the (anti)-Λ freezeout dynamics and the production mechanism of (anti)hypernuclei in relativistic heavy-ion collisions.

PACS numbers: 25.75.-q, 25.75.Dw, 21.80.+a

1. Introduction.—The recent observations of light antimatter in relativistic heavy-ion collisions at the Relativistic Heavy-Ion Collider (RHIC) $^{11}$ and Large Hadron Collider (LHC) $^{12}$ attract strong interest on the study of antimatter $^{11}$, and verify the general principles of quantum field theory which requires that each particle has its corresponding antiparticle and any physical system has an antimatter analog with an identical mass (but the opposite charge). These studies also provide the possibility to test the fundamental CPT theorem $^{10}$, to explore the interactions between antimatter and antihyperon $^{11,12}$, and to help hunting for antimatter and dark matter in the Universe through cosmic radiation observations $^{11}$. The antihelium-4 ($^{4}_Λ$He or $^{4}_Λ$He) is the heaviest antimatter nucleus observed so far $^{11}$, and it is of great interest to search for antihypernuclei heavier than $^{4}_Λ$He in heavy-ion collisions, which is extremely useful to understand the production mechanism of heavier antihypernuclei $^{4,10}$.

Collisions of heavy nuclei at high energies also provide an abundant source of (anti)strangeness $^{11}$ and a unique tool to produce light (anti-)hypernuclei $^{12}$. The STAR collaboration at RHIC reported the observation of hypertriton ($^{3}_Λ$H) and antihypertriton ($^{3}_Λ$He) in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV $^{11}$, and recently the ALICE collaboration at LHC also reported the observation in Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV $^{13}$. The value of measured yield ratio $^{3}_Λ$H/$^{3}_Λ$He is 0.82 ± 0.16(stat.) ± 0.12(syst.) for 0–80% centrality Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV (RHIC) $^{11}$ and 0.47 ± 0.10(stat.) ± 0.13(syst.) in central (0–10% centrality) Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV (LHC) $^{13}$. It is thus favored that the measured $^{3}_Λ$H/$^{3}_Λ$He ratio at RHIC is higher than that at LHC, although they are compatible with a very small overlap within the uncertainties by combining the statistical and systematic uncertainties, i.e., 0.82 ± 0.20 at RHIC and 0.47 ± 0.16 at LHC. The value of the $^{3}_Λ$H/$^{3}_Λ$He ratio for 0–80% centrality at RHIC (i.e., 0.82 ± 0.20) is expected to be further enhanced for central collisions since the ALICE measurements indicate that the $^{3}_Λ$H/$^{3}_Λ$He ratio in central Pb+Pb collisions is higher than that in peripheral Pb+Pb collisions $^{13}$. Similar conclusion is obtained for the $^{3}_Λ$He/$^{3}_Λ$He ratio for which the measured value is 0.89 ± 0.28(stat.) ± 0.13(syst.) for 0–80% centrality Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV $^{13}$ and 0.42 ± 0.10(stat.) ± 0.13(syst.) in central (0–10% centrality) Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV $^{13}$. As shown in Ref. $^{14}$, the conventional (statistical) thermal models $^{15,18}$ failed to describe the RHIC ratio, although some of them $^{15,17}$ successfully described the LHC ratio. The thermal model with a multi-freezeout configuration $^{18}$ reasonably described the ratio at RHIC but failed at LHC, and so did the parton and hadron cascade phase-space coalescence model $^{20,21}$. The dynamical $^{22}$ and simple $^{23,24}$ coalescence models described marginally the ratio at RHIC but no results are available at LHC. Therefore, the measured $^{3}_Λ$H/$^{3}_Λ$He and $^{3}_Λ$He/$^{3}_Λ$He ratios challenge all theoretical calculations performed so far and call for novel mechanisms for (anti-)hypernuclei production in these collisions.

Since hyperons have quite different interactions compared with nucleons $^{23}$, they are expected to have different freezeout dynamics in heavy-ion collisions, which will lead to distinct features for the production of light (anti)hypernuclei compared with that of light normal (anti)nuclei. In this work, we show that the covariant coalescence model can naturally reproduce the measured

\[ H^3/He \] at both RHIC and LHC if (anti-)\( \Lambda \) particles freeze out earlier than (anti)nucleons but their relative freezeout time is closer at LHC than at RHIC. The earlier anti-\( \Lambda \) \( (\bar{\Lambda}) \) freezeout leads to the heavier antihypernucleus \( \bar{\Lambda}/\bar{\Lambda} \) has a comparable yield with \( ^4\text{He} \) and thus provides an easily measured candidate for antihypermatter heavier than \( ^3\text{He} \).

2. Covariant coalescence model.—We use the covariant coalescence model \([25]\) for the production of light clusters in heavy-ion collisions. The main feature of the coalescence model \([27, 29]\) is that the coalescence probability depends on the details of the phase space structure of the constituent particles at freezeout as well as the statistical weight and internal structure (wave function) of the coalesced cluster, and these details are of no relevance in the thermal model \([13, 16, 30, 32]\) of cluster creation.

The phase space configuration of the constituent particles at freezeout is a basic ingredient in the coalescence model, and in principle it can be obtained dynamically from transport model simulations for heavy-ion collisions (see, e.g., Refs. \([33, 34]\)). For the particle production at mid-rapidity in central heavy-ion collisions at RHIC and LHC considered here, for simplicity, we assume a boost-invariant longitudinal expansion for the constituent particles which are emitted from a freezeout hypersurface \( \Sigma^\mu \), and the Lorentz invariant one-particle momentum distribution is then given by

\[
E \frac{d^3N}{d^3p} = \frac{d^3N}{p_x dp_x dp_y dy} = \int_{\Sigma} d\sigma_\rho p^\mu f(x, p, y) = \int d^4x S(x, p),
\]

where \( \sigma_\rho \) denotes the normal vector of hypersurface \( \Sigma^\mu \) and \( p^\mu \) is the four-momentum of the emitted particle. The emission function \( S(x, p) \) can be expressed by

\[
S(x, p) d^4x = m_T \cosh(\eta - y) f(x, p, y) J(\tau) \tau d\tau d\rho dr d\phi, \tag{2}
\]

where we use longitudinal proper time \( \tau = \sqrt{t^2 - z^2} \), spacetime rapidity \( \eta = \frac{1}{2} \ln \frac{1 + \gamma}{1 - \gamma} \), cylindrical coordinates \((r, \phi, z)\), rapidity \( y = \frac{1}{2} \ln \frac{E + p_T}{E - p_T} \), transverse momentum \((p_T, \phi)\), and transverse mass \( m_T = \sqrt{m^2 + p_T^2} \). The statistical distribution function \( f(x, p) \) is given by

\[
f(x, p, y) = g(2\pi)^{-3} \frac{\rho(\Delta T/\xi)}{[\exp(x - \rho)] \cdot \xi} \frac{1}{[\exp(x - \rho)]} \frac{1}{[\exp(x - \rho)]}
\]

with \( g \) being spin degeneracy factor, \( \xi \) the fugacity, \( \rho \) the four-velocity of a fluid element in the fireball, \( T \) the local temperature, and \( p^\mu u_\mu = m_T \cosh(\eta - y) - p_T \sinh(\phi - \phi_0) \) the energy in local rest frame of the fluid.

Following Ref. \([33, 34]\), we assume the freezeout time follows a Gaussian distribution \( J(\tau) = \frac{1}{\Delta \tau \sqrt{2\pi}} \exp(-\frac{\tau^2}{2\Delta \tau^2}) \) with a mean value \( \tau_0 \) and a dispersion \( \Delta \tau \), and the transverse rapidity distribution of the fluid element in the fireball is parameterized as \( p = \rho_0 r / R_0 \) with \( \rho_0 \) being the maximum transverse rapidity and \( R_0 \) the transverse radius of the fireball. The phase space freezeout configuration of the constituent particles is thus determined by six parameters, i.e., \( T, \rho_0, R_0, \tau_0, \Delta \tau \) and \( \xi \).

The cluster production probability is determined by the overlap of the cluster Wigner function with the constituent particle phase-space distribution at freezeout. If \( M \) particles are coalesced into a cluster, the invariant momentum distribution of the cluster can be obtained as

\[
E \frac{d^3N_c}{d^3p} = E g_c \int \left( \prod_{i=1}^{M} \frac{d^3p_i}{E_i} \right) d^4x S(x, p_1) \times \rho_c(x, p_1, ..., p_M) \delta^3(P - \sum_{i=1}^{M} p_i) \tag{3}
\]

where \( N_c \) is the cluster multiplicity, \( E \) (\( P \)) is its energy (momentum), \( g_c \) is the coalescence factor, and \( \rho_c \) is the Wigner function. In this work, the harmonic oscillator wave functions are assumed for all the clusters in the rest frame except the (anti)deutrons for which the Hulthén wave function is used (see, e.g., Refs. \([33, 34]\)), and so the cluster Wigner functions and root-mean-square radii \( r_{\text{rms}} \) can be obtained analytically. The details about how to calculate the integral \([35]\) can be found in Ref. \([10]\).

It should be stressed that since the constituent particles may have different freezeout times, the particles that freeze out earlier are allowed to propagate freely until the time when the last particles in the cluster freezes out to make the coalescence at equal time \( \tau_0 \).

3. Production of (anti)hypertiton.—The coalescence factor is given by \( g_c = \frac{2\pi}{\sqrt{\xi}} \) with \( j \) the spin and \( N \) the nucleon number of the nucleus. For \( d, ^3\text{He, } ^4\text{He and } 3/2^\text{He} \) that we focus on here, their spins are 1, 1/2, 1/2, 0 and 0, respectively, and their \( r_{\text{rms}} \) which are directly related to their Wigner functions \([10]\), are 1.96 fm, 1.76 fm, 4.9 fm, 1.45 fm and 2.0 fm, respectively \([33, 41]\). The (anti)(hyper)nuclei are assumed to have the same \( j \) and \( r_{\text{rms}} \) as their corresponding (hyper)nuclei.

Following Ref. \([10]\), the proton (p) freezeout parameters \( T, \rho_0 \) can be extracted from fitting the p spectrum, and the \( R_0, \tau_0, \Delta \tau \) and \( \xi_0 \) can be obtained by further fitting the spectra of \( d \) and \( ^3\text{He} \) in the coalescence model. For central Au+Au collisions at \( \sqrt{s_{NN}} = 200 \) GeV, we obtain \( T = 111.6 \) MeV, \( \rho_0 = 0.98, R_0 = 15.6 \) fm, \( \tau_0 = 10.6 \) fm/c, \( \Delta \tau = 3.5 \) fm/c and \( \xi_0 = 10.5 \) by fitting the p spectrum from PHENIX \([41]\) and the spectra of \( d \) and \( ^3\text{He} \) from STAR \([1]\), and for antiprotons \( \bar{p} \), we assume they have the same freezeout as protons except the fugacity is reduced to \( \xi_{\bar{p}} = 7.84 \) to describe the measured \( \bar{p}/p = 0.75 \) \([11]\). For central Pb+Pb collisions at \( \sqrt{s_{NN}} = 2.76 \) TeV, we obtain \( T = 121.1 \) MeV, \( \rho_0 = 1.215, R_0 = 19.7 \) fm, \( \tau_0 = 15.5 \) fm/c, \( \Delta \tau = 1.0 \) fm/c and \( \xi_{\bar{p}} = 3.72 \) by fitting the measured spectra of p, d, \( ^3\text{He} \) from ALICE \([1, 4, 42]\), and the antiprotons are assumed to have the same freezeout parameters as protons since the \( \bar{p}/p \) is close to unity at LHC. For neutrons \( n \) (antineutrons \( \bar{n} \)), we take their freezeout parameters as those of p's \( (\bar{p})'s \) since the isospin chemical potential at freezeout is small at RHIC and LHC \([15]\). The p freezeout parameters at RHIC (denoted by FOAu-N) and LHC (denoted by FOPb-N) are summarized in Table \([1]\) and the freezeout hypersurface at LHC is seen to have larger \( T, \rho_0, R_0 \) and \( \tau_0 \) but smaller \( \Delta \tau \) and \( \xi_{\bar{p}} \). In Fig. \([1]\) the experimental data are compared with the calculated re-
TABLE I: Parameters of various freezeout configurations for (anti)nucleons and (anti-)Λ particles at midrapidity in central collisions of Au+Au at \( \sqrt{s_{NN}} = 200 \) GeV (FOAu) and Pb+Pb at \( \sqrt{s_{NN}} = 2.76 \) TeV (FOPb). The unit of \( \tau_0 \) and \( \Delta \tau \) is fm/c, \( \xi \) and \( \bar{\xi} \) denote the fugacity of particles and antiparticles, respectively.

![FIG. 1: Transverse momentum distributions of p, d, \( ^3\)He, \( ^3\)H and \( ^4\)H at midrapidity in central collisions of Au+Au at \( \sqrt{s_{NN}} = 200 \) GeV (a) and Pb+Pb at \( \sqrt{s_{NN}} = 2.76 \) TeV (b) predicted by coalescence model with various freezeout configurations. For Au+Au collisions, the data of proton is taken from the PHENIX [14] and those of d and \( ^3\)He are taken from STAR [1]. The data of p, d, \( ^3\)He and \( ^4\)H for Pb+Pb collisions are taken from ALICE [4,14,42].](image)

Results for the spectra of p, d and \( ^3\)He with FOPb-N and FOPb-\( \Lambda \), and one can see that the coalescence model describes well the measured spectra. Table II lists the \( p_T \)-integrated yield in the midrapidity region (\( -0.5 \leq y \leq 0.5 \)) (i.e., \( dN/dy \)) for p (\( p_T \), d (\( d \)), \( ^3\)He (\( ^3\)He) and \( ^4\)He (\( ^4\)He) with FOPb-N and FOPb-\( \Lambda \), and it is seen that the \( dN/dy \) values of d, \( ^3\)He and \( ^4\)He (\( d \), \( ^3\)He and \( ^4\)He) at LHC are roughly two (four) times as large as those at RHIC.

For \( \Lambda \) particles, we first assume they have the same freezeout configuration as nucleons except that the \( \Lambda \) fugacity becomes \( \xi_{\Lambda} = 42.8 \) (9.54) at RHIC (LHC) by fitting the experimental \( \Lambda \) spectra [13,44] as shown in Fig. 2 by solid lines. The \( \Lambda \) particles are assumed to have the same freezeout parameters as \( \Lambda \) particles except the fugacity at RHIC is reduced to \( \xi_{\Lambda} = 35.1 \) to describe the measured \( \Lambda/p_\Lambda = 0.82 \) [43]. The (anti-)\( \Lambda \) freezeout parameters are listed as FOPb-\( \Lambda \) (FOPb-\( \Lambda \)) in Table II for the central Au+Au (Pb+Pb) collisions. With FOPb-\( \Lambda \) and FOPb-\( \Lambda \) (together with FOPb-N and FOPb-\( \Lambda \)), the spectra of \( ^3\)H and \( ^4\)H can then be calculated using the coalescence model, and the results are shown in Fig. 1. The \( dN/dy \) values for \( \Lambda \) (\( \Lambda \)), \( ^3\)H (\( ^3\)H) and \( ^4\)H (\( ^4\)H) are summarized in Table II and the resulting \( ^3\)H/\( ^4\)He is about 0.29 (0.24) at RHIC (LHC) with FOPb-\( \Lambda \) (FOPb-\( \Lambda \)), which significantly underestimates the measured values from STAR [13] and ALICE [14], i.e., 0.82\( \pm 0.16 \) (stat.) + 0.12 (syst.) for \( 0 \leq 80 \)% centrality Au+Au collisions at \( \sqrt{s_{NN}} = 200 \) GeV [13] and 0.47\( \pm 0.10 \) (stat.) + 0.13 (syst.) in central (0 \( - 10 \)% centrality) Pb+Pb collisions at \( \sqrt{s_{NN}} = 2.76 \) TeV [14]. The predicted ratio \( ^3\)H/\( ^4\)He is about 0.31 (0.24) at RHIC (LHC) with FOPb-\( \Lambda \) (FOPb-\( \Lambda \)), again significantly underestimating the measured values, i.e., 0.89 \( \pm 0.28 \) (stat.) \( \pm 0.13 \) (syst.) from STAR [12] and 0.42 \( \pm 0.10 \) (stat.) \( \pm 0.13 \) (syst.) from ALICE [14]. In addition, the predicted \( ^3\)H spectrum with FOPb-\( \Lambda \) is seen to underestimate the recently measured spectrum by ALICE [14].

To understand the disagreement of \( ^3\)H/\( ^4\)He (\( ^3\)H/\( ^4\)He)
and the $^3\text{H}$ spectrum between the predictions and the measurements, we extract the $\Lambda$ freezeout parameters $T$ and $\rho_0$ by directly fitting the measured $\Lambda$ spectra as shown in Fig. 2 by dashed lines, and we obtain $T = 126$ (123.4) MeV and $\rho_0 = 0.89$ (1.171) for Au+Au (Pb+Pb) collisions, which better describe the data than FOAu-Λ (FOPb-Λ). The $\Lambda$ particles thus have a higher freezeout temperature than nucleons, especially at RHIC, implying an earlier freezeout for $\Lambda$ particles than for nucleons, which is consistent with the empirical picture that the strange baryons usually freeze out earlier than the nonstrange baryons due to their relatively smaller interaction interaction cross sections. The earlier $\Lambda$ freezeout is also supported by the investigation on strangeness production as well as the microscopic transport model simulations.

An earlier $\Lambda$ freezeout means the $\Lambda$ particles can pick up unfrozen-out nucleons to form light hypernuclei, and this implies the nucleons coalesced into light hypernuclei also have an earlier freezeout time than those coalesced into normal light nuclei. To consider this effect, for the coalescence production of light hypernuclei, we reduce the $\tau_0$ and $R_0$ simultaneously but increase the $\xi$ to fit the $\Lambda$ and p spectra. In this way, the earlier freezeout increases the phase space density of $\Lambda$, p and n, and thus the $^3\text{H}$ production rate. To fit the measured central value $0.82$ (0.47) of the $^3\text{H}/^3\text{He}$ ratio at RHIC (LHC), we find the $R_0$ and $\tau_0$ need to be reduced to 71% (85%) of their values in FOAu-Λ (FOPb-Λ), i.e., $R_0 = 11.1$ (16.7) fm and $\tau_0 = 7.54$ (13.1) fm/c, if we fix $T = 126$ (123.4) MeV, $\rho_0 = 0.89$ (1.171) and $\Delta \tau = 3.5$ (1.0) fm/c. These new freezeout configurations are denoted as FOAu-$\Lambda^*$ and FOPb-$\Lambda^*$ in Table II. It is interesting to note that the $\Lambda$ freezeout temperature is slightly higher at RHIC than at LHC. For FOAu-$\Lambda^*$ and FOPb-$\Lambda^*$, we have neglected final state interactions of the produced $^3\text{H}$ during the last 2 ~ 3 fm/c time interval when some nucleons have not yet frozen out, and probably this can be justified from the transport model study which indicates including the final state interactions changes the deuteron yield by only about 20% at RHIC [36]. On the other hand, since $^3\text{H}$ is an even more loosely bound system than deuteron (Note the total binding energy of $^3\text{H}$ is 2.354 MeV with the $\Lambda$ separation energy of only about 0.13 MeV [50]), and the total binding energy of deuteron is 2.224 MeV [51]), the effects of the final state interactions on $^3\text{H}$ yield are thus expected to be stronger than that on deuteron. For $^3\text{H}$, the total binding energy is 10.601 MeV with the $\Lambda$ separation energy of 2.12 MeV [52], and the effects of the final state interactions are thus expected to be similar with the case of deuteron. The quantitative information on the final interaction effects needs a complicated transport model simulations. The stronger final state interaction (destruction) of $^3\text{H}$ implies the $\Lambda$ particles need an even earlier freezeout than that obtained above, and the effects of an earlier $\Lambda$ freezeout in the present work are thus considered to be conservative estimate.

The predicted spectra of $^3\Lambda\text{H}$ and $^3\text{H}$ with FOAu-$\Lambda^*$ and FOPb-$\Lambda^*$ are shown in Fig. 1 by dashed lines, and one can see that compared with FOAu-Λ and FOPb-Λ, FOAu-$\Lambda^*$ and FOPb-$\Lambda^*$ significantly enhance the production of $^3\Lambda\text{H}$ and $^3\text{H}$ and now the $^3\text{H}$ spectra measured by ALICE [13] can be reasonably described by FOPb-$\Lambda^*$. The $dN/dy$ values for $\Lambda (\Lambda)$, $^3\Lambda\text{H} (\Lambda\Lambda)$ and $^3\text{H} (\Lambda\Lambda)$ with FOAu-$\Lambda^*$ and FOPb-$\Lambda^*$ are listed in Table III. The small difference for the $dN/dy$ of (anti)-$\Lambda$ between FOAu-$\Lambda^*$ (FOPb-$\Lambda^*$) and FOAu-Λ (FOPb-Λ) is due to the slight variation of the $\Lambda$ spectra from different fits as shown in Fig 2. The calculated $^3\text{H}/^3\text{He}$ and $^3\Lambda\text{H}/^3\text{He}$ ratios are, respectively, about 0.83 (0.47) and 0.91 (0.47) at RHIC (LHC) with FOAu-$\Lambda^*$ (FOPb-$\Lambda^*$), nicely reproducing the measured central values. Therefore, our results suggest that (anti)-$\Lambda$ particles may freeze out earlier than (anti)nucleons but their relative freezeout time is closer at LHC than at RHIC. It is interesting to see that the $\Lambda$ and nucleon freezeout parameters seem to come close to each other as the energy increases and this is understandable since a higher collision energy generally leads to a longer-lived hadronic fireball where the $\Lambda$’s and nucleons will experience more collisions.

The ratio $S_3 = ^3\Lambda\text{H}/(2^3\text{He}\Lambda/p)$ was first suggested in Ref. [53] in the expectation that dividing the strange to nonstrange baryon yield should result in a value near unity in a naive coalescence model. It was also argued to be a good representation of the local correlation between baryon number and strangeness [54], and thus should be a valuable probe for the onset of deconfinement in relativistic heavy-ion collisions. The $S_3$ was measured to be $1.08 \pm 0.22$ for 0-80% centrality Au+Au collisions [13] and $0.60 \pm 0.13$ (stat.) $\pm 0.21$ (syst.) for central (0-10% centrality) Pb+Pb collisions [13]. For central collisions considered here, the $S_3$ for Au+Au (Pb+Pb) collisions is 0.27 (0.33) with FOAu-Λ (FOPb-Λ), while it increases to 0.71 (0.61) with FOAu-$\Lambda^*$ (FOPb-$\Lambda^*$). The FOAu-Λ (FOPb-Λ) thus significantly underestimates the measured $S_3$ for Au+Au (Pb+Pb) collisions. While FOPb-$\Lambda^*$ nicely reproduces the measured $S_3$ for Pb+Pb collisions, the FOAu-$\Lambda^*$ still underestimates the measured $S_3$ for Au+Au collisions. It should be noted that while there is negligible feed-down from heavier states into $^3\Lambda\text{H}$ and $^3\text{He}$, the $\Lambda$ and p are significantly influenced by feed-down from decays of excited baryonic states. In the coalescence model calculations, the $\Lambda$ and p from the short-lived strong decays are included since they appear in the fireball, while those from the other long-lived decays are excluded since they are out of the fireball. In the calculation of the $S_3$ for Au+Au collisions, we use the p spectrum from PHENIX [41] which is corrected by excluding the contribution from the long-lived weak decays. We note that including 40% contribution from weak decays to the p yield leads to $S_3 = 0.994$ for Au+Au collisions with FOPb-$\Lambda^*$, consistent with the measured value from STAR.

It should be pointed out that although the $\Lambda$’s and nucleons are assumed to have the same freezeout configuration, the $S_3$ is still significantly less than unity (e.g.,
is interesting to see that the collisions of Au+Au at √sNN = 200 GeV and Pb+Pb at √sNN = 2.76 TeV from the coalescence model with various freezeout configurations. The stars (squares) indicate the empirical size values r rms = 4.9 (1.76) fm for 3H (3He).

S3 = 0.27 (0.32) for FOAu-Λ (FOPb-Λ). This is mainly due to the much larger size of 3H than that of 3He, as suggested first in Ref. 53. To see this more clearly, we show in Fig. 3 the predicted dN/dy of 3H and 3He as a function of their root-mean-square radii in central collisions of Au+Au at √sNN = 200 GeV and Pb+Pb at √sNN = 2.76 TeV from the coalescence model with various freezeout configurations. The empirical size values, i.e., r rms = 4.9 fm for 3H and r rms = 1.76 fm for 3He are also indicated in Fig. 3. It is seen that, because of the finite size cut off effect of the fireball in the spatial part integration of Eq. 3, the dN/dy decrease with r rms when r rms is larger than about 1.6 fm. Furthermore, it is interesting to see that the dN/dy exhibits a stronger r rms dependence at RHIC than at LHC, and this is mainly due to the fact that the freezeout volume (πR0 3N/2) is smaller at RHIC. Compared with the thermal model, the coalescence model thus has a distinct feature that the cluster yield depends on the cluster size, as mentioned earlier. Assuming 3H has a same r rms as 3He, i.e., r rms = 1.76 fm, we find that the S3 values for both Au+Au (with FOAu-Λ) and Pb+Pb (with FOPb-Λ) collisions are drastically enhanced to about 0.85, and further to unity if the Λ’s and nucleons are assumed to have equal mass, as expected from the naive coalescence model.

4. Production of 4He (3H).—The 4He is a well-researched hypernucleus with lifetime of 192+20−15 ps 52 and mass M(4He) = 3922.484 ± 0.01 (stat.) ± 0.09 (syst.) MeV 52 (Note the mass of 4He is M(4He) = 3727.379 MeV). The 4He can be identified through the 4He−π− invariant mass spectrum from the decay 4He → 3He + π− with branching ratio of about 50% 50,57.

Shown in Fig. 4 are the predicted dN/dy of light (anti)(hyper)nuclei as a function of dN/dy/m, where B is the baryon number of light clusters and m is the corresponding mass, in central collisions of Au+Au at √sNN = 200 GeV and Pb+Pb at √sNN = 2.76 TeV from the coalescence model with various freezeout configurations. The squares in (a) represent the results for 4He and 4He in the Au+Au collisions by considering the binding energy effects to fit STAR data 10 while the square in (b) is the preliminary result for 4He in 0−20% centrality Pb+Pb collisions from ALICE measurement 53.

Furthermore, it is seen from Fig. 4 that compared with FOAu-Λ (FOPb-Λ), FOAu-Λ (FOPb-Λ) significantly enhances the dN/dy of (anti) 3H and (anti) 4He due to the earlier Λ freezeout. From the detailed numbers listed in Table 1 one can see that in Au+Au collisions, the dN/dy of 4He (3H) is 1.48×10−7 (5.12×10−8) with FOAu-Λ and 1.57×10−6 (5.43×10−7) with FOAu-Λ, implying the earlier Λ freezeout enhances the yields...
of both $^{1}\text{H}$ and $^{4}\text{He}$ by a factor of 10.6. In Pb+Pb collisions, the $dN/dy$ of $^{1}\text{H}$ (same for $^{4}\text{He}$) is $1.36 \times 10^{-7}$ with FO$^{2}\text{Pb-A}$ and $5.43 \times 10^{-7}$ with FO$^{4}\text{Pb-A}$, and the enhancement factor due to the earlier $\Lambda$ freezeout is 4.0. It is interesting to see that the $dN/dy$ of $^{1}\text{H}$ ($^{4}\text{He}$) at RHIC is larger than at LHC. The earlier (anti-)$\Lambda$ freezeout can significantly enhance the yield of $^{1}\text{H}$ ($^{4}\text{He}$), leading to that $^{4}\text{He}$ provides an easily measured candidate for antimat matter heavier than $^{2}\text{He}$. The larger relative p-$\Lambda$ (p-He) freezeout time difference at RHIC leads to a larger (equal) yield of $^{1}\text{H}$ ($^{4}\text{He}$) at RHIC than at LHC. In future, more precise measurement on $^{1}\text{H}/^{4}\text{He}$ and $^{4}\text{He}/^{2}\text{He}$ as well as the measurement on $^{1}\text{H}$ and $^{4}\text{He}$ would be extremely helpful to test the proposed freezeout scenario for (anti-)$\Lambda$ particles and the predictions on light (anti-)hypernuclei production presented in this work.
