ABSTRACT

The seven seconds’ gap in the Kamiokande-II SN1987A neutrino data is reexamined.

1. SN1987A NEUTRINO BURST DATA

The Kamiokande-II collaboration successfully observed the neutrino burst from SN1987A, detecting eleven neutrino events over ∼13 s (Hirata et al. 1987). This observation was also confirmed by the IMB collaboration (Bionta et al. 1987).

The Kamiokande-II SN1987A events have a curious time structure, known as the “seven seconds’ gap”. Between the 9th and 10th events, there was a gap of 7.304 s, as shown in Fig. 1. The IMB collaboration found three neutrino events in that period, and the time gap was not due to the absence of the neutrino flux (Bionta et al. 1987; Hirata et al. 1988). Assuming a uniform neutrino flux, the probability of observing a seven seconds’ gap is less than 5% (Hirata 1988). However, no reasonable explanation for the gap, other than a chance coincidence, has been found.

In the 7.304 s gap, you can find no cosmic ray muon events, whose rate is ~0.37 Hz. Surprisingly, no cosmic ray muon event was detected in ∼13 s of the supernova neutrino period! In addition, you can find no low energy background events (mostly coming from radio activities), whose rate is ~0.15 Hz.

Let me pull your attention to the gap again

Figure 1. Time structure of the Kamiokande-II events in the SN1987A period. The original plot is shown in FIG.2 of Hirata et al. (1987). The time period of the seven seconds’ gap is also shown.

This study points out that no other categories of events were detected during the 7.304 s gap. As shown in Fig. 1, no cosmic ray muon event with a rate of 0.37 Hz was detected. Interestingly, no cosmic ray muon event was detected in ∼13 s of the entire SN1987A neutrino period. Furthermore, no low-energy background event, which mostly originates from radioactivity with a rate of 0.15 Hz, was detected.

The probabilities of detecting no SN1987A neutrino, no cosmic ray muon and no low energy background in Δt = 7.304 s are listed in Table 1. From these, the overall probability (P) that none of these events was detected can be calculated as

P < 0.05 × 0.067 × 0.334 = 0.00112.

A value as low as P < 0.112% is unlikely to be due to a chance coincidence. Therefore, it is natural to consider a possible dead time of the Kamiokande-II detector.

2. POSSIBLE DEAD TIME

The block diagram of the Kamiokande-II data acquisition is shown in FIG.2 of Hirata et al. (1988). The original data were directly recorded onto 2400 feet, 6250 byte-per-inch open-reel magnetic tapes (MTs) because of the small capacity of the hard disks. When the data were recorded, “write error” occasionally occurred. Partial rewind and retry were automatically performed, and the recovery took ~10 s. During that time, the data buffers in the computer memory might become full, and no new data could be accepted. In fact, the Kamiokande-II shift manual had the following instructions: To avoid frequent write error, clean the head of the MT recorder using isopropyl alcohol when mounting MTs. The rate of the write error primarily depended on the cleanliness of the head of the MT recorder.
Table 1. Calculation of the probabilities that no event was detected in the 7.304 s time period. The probability for SN1987A neutrinos was obtained from Hirata (1988). Other probabilities were obtained using the Poisson probability function \( P(\text{0 event}|\lambda) = e^{-\lambda} \frac{\lambda^0}{0!} \).

| Rate (Hz) in 7.304 s | Expected # calculation | Probability of 0 event |
|----------------------|------------------------|------------------------|
| SN1987A \( \nu \)   | K.S.Hirata < 0.05      |
| cosmic ray \( \mu \) | Po\(i(0|2.70)\) 0.067 |
| low energy B.G.      | Po\(i(0|1.10)\) 0.334 |

and status of the MTs. If the memory of the author is correct, the rate of the error was on the order of once per hour. The “write error and retry” could explain the origin of the seven seconds’ gap, even though it cannot be verified.

In Hirata et al. (1987), it was reported that the \( \bar{\nu}_e \) output of SN1987A is estimated to be \( 8 \times 10^{52} \) ergs. If the seven seconds' gap is dead time and it is assumed that similar number of neutrino events is expected during this dead time, the \( \bar{\nu}_e \) output of SN1987A should be larger by a factor \( \sim 2 \).

To summarize, the probability of the Kamiokande-II experiment detecting “no SN1987A neutrino”, “no cosmic ray muon” and “no low energy background” for 7.304 s is less than 0.112%. The possibility that the seven seconds' gap was seven seconds' dead time of the Kamiokande-II data acquisition cannot be excluded.
