Abstract

Objective: To determine the prevalence of virological failure and HIV drug resistance among Chinese patients one year after initiating lamivudine-based first-line antiretroviral treatment.

Methods: A prospective cohort study with follow-up at 12 months was conducted in four urban sentinel sites in China. Antiretroviral naïve patients ≥18 years old were recruited. Blood samples were collected for testing CD4 cell count, viral load, and (for samples with HIV-1 RNA ≥1000 copies/ml) genotyping of drug resistance.

Results: A total of 513 patients were enrolled in this cohort, of whom 448 (87.3%) were retained at 12 months. The median final CD4 cell count was 313 cells/mm³, which increased from 192 cells/mm³ at baseline (P < 0.0001). Of the 448 remaining subjects, 394 (87.9%) had successful virological suppression (HIV RNA <1000 copies/ml). Among 54 samples with viral load ≥1000 copies/ml, 40 were successfully genotyped, and 11 were found with detectable HIV drug resistance mutations. Of these, the proportions of drug resistance to NNRTIs, NRTIs and PIs were 100%, 81.8% and 0%, respectively. Injecting drug use (AOR = 0.40, 95% CI: 0.19, 0.84; P = 0.0154), CD4 count at baseline ≥350 cells/mm³ (AOR = 0.32, 95% CI: 0.14, 0.72; P = 0.0056), and missed doses in the past month (AOR = 0.30, 95% CI: 0.15, 0.60; P = 0.0006) were significantly negatively associated with HIV RNA <1000 copies/ml.

Conclusions: Our study demonstrates effective virological and immunological outcomes at 12 months among those who initiated first-line ART treatment. However, patients infected through drug injection, who missed doses, or with higher CD4 count at baseline are at increased risk for poor virological response.

Introduction

The rapid expansion of combination antiretroviral treatment (cART) has dramatically improved the prognosis of patients infected with HIV and decreased HIV/AIDS associated morbidity and mortality [1–5]. Since year 2000, most developing countries have initiated cART treatment programs, many of which were scaled-up in 2003 through the “3 by 5” initiative. At the end of 2011, more than 8 million people in low- and middle-income countries were receiving antiretroviral therapy (ART), up from 6.6 million in 2010 which represented an increase of about 20% [6].

Since the China’s National Free Antiretroviral Treatment Program (NFATP) began in 2002, cART use has scaled up rapidly. By the end of 2012, more than 208,216 patients across the country had received free antiretroviral treatment [7]. Many studies found that the NFATP has successfully increased life expectancy and reduced mortality among Chinese HIV patients [8–11]. However, although rapid cART scale-up significantly decreased AIDS-related morbidity and mortality, HIV antiretroviral treatment programs are facing the challenge of potential widespread emergence and transmission of HIV drug resistance (HIVDR) [11–15].
In 2004, The World Health Organization (WHO), in collaboration with the United States Centers for Disease Control and Prevention (CDC) and through HIVResNet developed a global strategy for the assessment and prevention of HIVDR. The protocol for population-based surveillance of acquired HIVDR at sentinel ART clinics is designed to be used particularly in resource-limited countries, where decisions on ART regimens for a given patient population are made through monitoring HIVDR emergence during treatment in addition to related program factors [16]. In China, based on the WHO HIVDR surveys under the direction of the Ministry of Health HIVDR working group, studies have shown that community-based ART had significant effects on viral suppression and acquired HIVDR at six sentinel sites in China [17–18]. However, the NFATP’s first-line antiretroviral regimens have since been changed to exclude the use of didanosine (DDI) and to include the use of lamivudine (3TC) for all new patients initiating treatment [19]. Due to these changes and the rapid scale-up of ART in China, the aim of this prospective study is to evaluate HIVDR in a cohort of Chinese HIV patients recently initiating 3TC-based first-line ART at four sentinel sites in 2011–2012.

Methods

Study Design and Study Participants

The four sentinel surveys were conducted in urban areas of China, including Jiangsu province (Nanjing, Suzhou, and Nantong cities), Guizhou province (Guiyang, Tongren, and Dujun cities), Hunan province (Hengyang City) and Chongqing Municipality (Shapingba, Jiulongpo, and Yuzhong districts), respectively, where most of HIV infection were transmitted through heterosexual intercourse and homosexual intercourse [7]. The survey was a prospective cohort study with follow-up at 12 months. The study subjects were recruited through sequential sampling at each clinic to participate in a one-year prospective cohort study. Criteria for enrolling in the study were: previously antiretroviral naive, 18 years or older, agreeing to initiate ART in the NFATP, and willing to provide informed consent. A baseline screening survey was conducted in 2011. The national treatment criterion at that time was: (1) CD4 cell count <350/mm³; (2) World Health Organization (WHO) stage III/IV diseases, or (3) willingness to receive ART, regardless of the criteria 1 and 2. The ART regimen will be provided through the NFATP. First-line ART regimen consisted of tenofovir (TDF) or azidothymidine (AZT) + lamivudine (3TC) + efavirenz (EFV) or nevirapine (NVP) [19]. The main study outcome was HIVDR emergence after the first year of ART. The specific objectives were to: (1) estimate the proportion of HIV RNA suppression to <1000 copies/ml and associated factors at 12 months after starting first-line ART, and (2) identify the prevalence of specific HIVDR mutations among those with viral load ≥1000 copies/ml [16].

Ethics Statement

The study was approved by the institutional review board of the National Center for AIDS/STD Control and Prevention of the China Center for Disease Control and Prevention (NCAIDS, China CDC).

Data Collection

Data were collected using an interviewer-administered questionnaire. Each study participant was assigned a confidential identification number used to label questionnaires and blood specimens. The questionnaire was administered by trained interviewers in a private room. Questionnaires included demographic data, ART treatment and self-reported adherence data. Demographic variables included age, sex, ethnicity, education level, marital status, occupation and HIV transmission route. ART treatment variables included WHO clinical stage, initial regimen, ART distribution institution, ART refill interval, missed ART doses in the past month, ratio of on-time drug intake in the past month, and reasons for loss of treatment retention.

Laboratory Tests

All subjects provided blood specimens for testing CD4+ T-lymphocyte count (CD4 count), HIV viral load, and HIV drug resistance mutations at baseline and 12-month follow-up. CD4 count was tested using flow cytometry (FACSC Calibur, BD Company, USA), within 24 hours after specimen collection in local CDCs. Blood plasma was isolated and stored frozen at −80°C at local CDCs before transferring to NCAIDS in Beijing for testing viral load and drug resistance mutations. Plasma HIV RNA was quantified with real-time NASBA (NucliSense Easy Q, bioMérieux, France) or with COBAS (Roche Applied Systems, Germany) according to the manufacturers’ recommendations. For the WHO surveys, successful viral suppression was defined as HIV RNA level <1,000 copies/ml using a quality-assured viral load assay. In samples with viral load ≥1,000 copies/ml, HIV drug resistance genotyping was performed at the WHO Accreditation Laboratory of NCAIDS, China CDC by using an in-house method as previously described [17–18]. Drug resistance mutation analysis and viral subtype determination were performed on a 1.3 kb section of the HIV pol gene using the Stanford University HIV Drug Resistance Database online sequence analysis tool (http://hivdb.stanford.edu/pages/algs/sierra_sequence.html). We included mutation results that conferred low-, intermediate-, and high-level resistance [20–22].

Data Analysis

Questionnaire and laboratory data were double-entered and compared using EpiData software (The EpiData Association Odense, Denmark). Data were then converted and analyzed using Statistical Analysis System version 9.1 (SAS Institute Inc., Cary, NC, USA). The data were analyzed using unadjusted odds ratios with a test for significance according to chi-square test and Fisher’s exact test. Variables that were significantly (p<0.05) associated with HIV RNA <1000 copies/ml at 12 months in the univariable analyses were considered for inclusion in the multivariable logistic regression model. Multivariable logistic regression was performed to examine the independent effect of each factor under consideration. All tests of significance were two-sided, with p-value < 0.05 indicating that an association was statistically significant.

Results

Demographic Characteristics

Among 535 consecutive participants enrolled, one was less than 18 years old, three refused to participate in the study, five did not receive national free regimen, and 13 patients with baseline HIVDR were excluded from this study. Thus, 513 subjects entered this prospective cohort and provided written informed consent. The baseline and 12-month follow-up characteristics were shown in Table 1. Of 513 eligible patients, 139, 123, 119 and 132 participants were from Jiangsu, Guizhou, Hunan, Chongqing, respectively; 78.6% were male; the mean age were 38.3 years (SD, ±11.2 years); 90.1% belonged to the Han ethnic group; 47.0% had education level of junior high school or lower; 48.2% were infected through heterosexual intercourse; and the most common HIV viral subtype was CRF01_AE.
Table 1. Characteristics of HIV patients receiving first-line ART in four sentinel antiretroviral treatment sites.

| Characteristics                      | Jiangsu | Guizhou | Hunan | Chongqing | Total       |
|--------------------------------------|---------|---------|-------|-----------|-------------|
|                                      | N (%)   | N (%)   | N (%) | N (%)     | N (%)       |
| Overall                              | 139     | 123     | 119   | 132       | 513         |
| Age (mean ± SD, year)                | 39.7 ± 11.3 | 34.5 ± 8.6 | 41.5 ± 10.1 | 39.4 ± 12.9 | 38.8 ± 11.2 |

HAART Regimens and Immunologic Profiles

All patients received free standard first-line regimen through the NFATP, and 98.4% maintained the initial regimen at follow-up. Only 7 (1.6%) patients switched to the second-line regimen during the follow-up. The initial ART regimen were AZT+3TC+NVP (59.1%), D4T+3TC+NVP (6.4%), AZT+3TC+EFV (14.4%), D4T+3TC+EFV (9.5%), 3TC+TDF+EFV (9.2%) and 3TC+TDF+NVP (1.4%). Among 65 participants who were lost to follow up, 4.9% had died, 4.9% were lost to contact, and 0.2% transferred out of the study districts (Table 1).

Of the 448 patients retained at 12 month, CD4 cell count was 313 cells/mm³, which increased from the median 192 cells/mm³ at baseline (P<0.0001). 14.1% reported missing doses, and 83.9% maintained ≥95% of on-time drug intake in the past month.

Genotypic Drug Resistance and Predictors for Viral Suppression Success

After receiving ART for nearly one year, 394 (87.9%) patients had plasma HIV RNA <1000 copies/ml. Among the 54 samples with viral load ≥1000 copies/ml, 40 were successfully genotyped. Of the 11 with detectable HIVDR mutations, the proportion of drug resistance to NNRTIs, NRTIs and PIs were 100%, 81.8% and 0%, respectively. Among these, 9 (81.8%) patients had multi-drug resistance to NNRTIs and NRTIs. The most common NNRTIs mutation site were K103N (36.4%), Y818C/I/V (27.3%) and K101E (18.2%). As well, M184V/I (72.7%), K65R (27.3%), D67N (27.3%) were found as the most frequent mutations to NRTIs (Table 2).

The factors significantly associated with successful viral suppression at 12 month were analysed through univariable logistic regression (Table 3). HIV transmission route, CD4 count at baseline, and missed doses in the past month were independent risk factors associated with virological failure (HIV RNA ≥1000 copies/ml). These three factors remained in the multivariable logistic regression model. Injecting drug use [adjusted odds ratio (AOR) = 0.40,95% CI: 0.19,0.84; P = 0.0154], CD4 count at baseline ≥350 cells/mm³ (AOR = 0.32,95% CI: 0.14,0.72; P = 0.0056), and missed doses in the past month (AOR = 0.30,95% CI: 0.15,0.60;P = 0.0006) were negatively associated with virological success.

**Discussion**

In this one-year prospective follow-up survey on HIVDR at sentinel sites in four Chinese provinces, viral load suppression (HIV RNA <1000 copies/ml) was achieved at 12 months in 87.9% of treated patients, with a range from 82.9% to 93.6%. This demonstrated a rapid but successful scale up of China’s NFATP. In the 2012 WHO drug resistance surveillance guideline, viral load suppression after 12 months of ART can be graded as poor (<70%), fair (70–85%), or excellent (>85%) [16]. All sentinel sites in our study met the excellent grade, and the overall suppression rate was comparable to treatment responses seen in other developing and developed countries [23–29]. As well, our previous surveillance studies in four and two sentinel sites in China showed that viral load suppression at 12 months was ≥70% and ≥85%, respectively [17,18]. Together, these HIVDR sentinel surveys indicated that virological failure did not increase over time during recent years of the NFATP’s expansion, when approximately 50,000 ART-naïve HIV patients initiated treatment each year. Our findings also provide support to the argument that the current WHO target of >70% viral load suppression at 12 months of treatment for low- and middle-income countries can be revised upwards, to such a rate as 85% [16].

The drug resistance mutations identified concurred with expected mutation patterns from a treatment program based on NNRTI and NRTI class drugs. Among patients with virological failure, 11 cases (27.5%) displayed NNRTI mutations and 9 cases (22.5%) displayed NRTI mutations. No protease inhibitor (PI) mutations were identified, which affirms that the continued use of PIs as second-line therapy is still viable in China. Our HIVDR results are comparable to reported values in other developed and developing countries [23–29].

Our study found that injecting drug use, baseline CD4 count ≥350, and missed doses in the past month were independently associated with virological failure (HIV RNA ≥1000 copies/ml) among HIV patients receiving free first-line ART in China. Virological failure as a result of poor adherence indicates that strengthening education and counseling among HIV patients should be an important priority for HIVDR prevention in China [14,30]. Training for health care providers should also be improved, especially among those with fewer resources to new treatment technology. Another concern was the high proportion of virological failure among injection drug users (IDUs) [17,31]. Low uptake of MMT and needle exchange services and high syphilis incidence suggest that large numbers of IDUs engaged in high-risk practices and may have transmitted HIVDR to others [32]. Efforts should be made to scale up IDU services to enhance ART adherence, and harm reduction programs should be considered as an essential part of HIV treatment. Additional data is needed for understanding how the dual treatment systems for HIV and drug addiction can be successfully integrated to reduce death and transmission of blood infections.

Lastly, the association of higher CD4 cell count with virologic failure warrants further investigation. Recent WHO guideline changes and advocacy towards initiating ART treatment at higher CD4 levels (≥500 cells/mm³ or immediately after testing) [33,34] have raised concerns for adherence in asymptomatic individuals. Evidence on this issue currently remains sparse internationally and has tended to show that early treatment leads to virological and clinical benefits [35,36]. However, a large study in China has also shown that patients with higher CD4 cell counts (≥500 cells/mm³) at ART initiation were more likely to drop out of HIV care [37]. Here in our cohort, the rate of loss to follow-up (including transfers out of the study follow-up districts) among patients with CD4 cell counts ≥350 cells/mm³ and <350 cells/mm³ were 8.9%(5/54) and 7.7%(3/40), respectively(p = 0.77). Although the difference is not statistically significant, the sample size of patients with higher CD4 cell count is small, and more data is needed to confirm the observed relationship. In general, further studies are needed to clarify the effects of early ART initiation on adherence and attrition at short-term versus long-term treatment timescales in China.

This study has some limitations. First, due to limited geographic distribution of the sentinel sites and participant exclusion criteria, these results may not be fully representative of all of China. Second, the overall retention rate at 12 months was 87.3%, but only 79.0% in Hunan province; results should therefore be interpreted with caution. Third, due to a relatively low rate of successful HIVDR sequencing, the HIVDR rate from this study is likely lower than the true drug resistance rate. Finally, a 12-month follow up survey is relatively short for the purposes of monitoring HIVDR, and more studies with long-term monitoring is recommended to provide more objective and accurate data on...
viral suppression, HIVDR incidence, and optimal choices of regimen. In sum, this HIVDR surveillance study in four sentinel sites across China demonstrates good virological and immunological outcomes at 12 months among those who initiated first-line ART treatment. However, patients infected through drug injection, who missed doses, or with higher CD4 at baseline are at increased risk for poor virological response. More data from these high-risk patients are needed to evaluate clinical outcomes and long-term effects of treatment.
