Abstract
Aim: Although cardiopulmonary exercise testing (CPET) is considered the gold standard, a preoperative abdominal CT scan might also provide information concerning preoperative aerobic fitness for risk assessment. This study aimed to investigate the association between preoperative CT-scan-derived body composition variables and preoperative CPET variables of aerobic fitness in colorectal surgery.

Method: In this retrospective cohort study, CT images at level L3 were analysed for skeletal muscle mass, skeletal muscle radiation attenuation, visceral adipose tissue (VAT) mass and subcutaneous adipose tissue mass. Regression analyses were performed to investigate the relation between CT-scan-derived body composition variables, CPET-derived aerobic fitness and other preoperative patient-related variables. Logistic regression analysis was performed to predict a preoperative anaerobic threshold (AT) ≤ 11.1 ml/kg/min as cut-off for having a high risk for postoperative complications.

Results: Data from 78 patients (45 men; mean [SD] age 74.5 [6.4 years]) were analysed. A correlation coefficient of 0.55 was observed between absolute AT and skeletal muscle mass index. Absolute AT ($R^2$ of 51.1%) was lower in patients with a lower skeletal muscle mass index, together with higher age, lower body mass and higher American Society of Anesthesiologists (ASA) score. Higher ASA score (odds ratio 5.64; $P = 0.033$) and...
INTRODUCTION

Colorectal cancer is the third most common type of cancer [1]. After resection for colon or rectal carcinoma, 15% and 20% of the patients respectively have a complicated course within 30 days after surgery, which might lead to a prolonged hospital stay of >14 days or even mortality [2]. Reducing complications will result in considerable cost savings [3]. Preoperative risk assessment might identify patients at high risk of postoperative complications; these patients may benefit from preoperative preventive interventions (prehabilitation) [4,5].

Cardiopulmonary exercise testing (CPET) is increasingly utilized for risk assessment before major surgery to evaluate the risk of adverse perioperative events [5]. CPET is an objective and precise method of evaluating a patient’s preoperative aerobic fitness. In general, patients with a lower oxygen uptake at the anaerobic threshold (AT) and/or a lower oxygen uptake at peak exercise (VO$_{2peak}$) have an increased risk of postoperative complications [6–9]. Despite its usefulness in perioperative medicine, CPET is not always available in clinical practice, is relatively expensive and time-consuming, and requires well-trained personnel for an adequate interpretation of its results.

For preoperative risk assessment, measurements of body composition using the routinely performed abdominal CT scan are increasingly gaining ground. Sarcopenia [10], a low skeletal muscle radiation attenuation (SM-RA) [11,12] and a high visceral adipose tissue (VAT) mass [13,14] have all been reported to be associated with poor clinical outcome following abdominal surgery. Furthermore, Boo and others [15] demonstrated that skeletal muscle mass is closely associated with aerobic fitness (the AT and VO$_{2peak}$) in community-dwelling elderly men, while a recent study by West and others [16] in patients undergoing hepatopancreatobiliary surgery reported that SM-RA and not skeletal muscle mass (assessed by a preoperative CT scan) were associated with aerobic fitness (assessed with preoperative CPET).

Although CPET is the gold standard to assess aerobic fitness, it would be of interest for time and cost savings to investigate whether the routinely performed preoperative abdominal CT scan can assist to preselect unfit patients. Therefore, the aim of this study was to preoperatively investigate the association between body composition variables derived from the abdominal CT scan and CPET variables of aerobic fitness in patients scheduled for colorectal surgery.

METHOD

The present retrospective study was reported according to the STrengthening the Reporting of OBservational studies in Epidemiology (STROBE) guideline.

Participants

Data from all patients ≥60 years old with colorectal cancer or dysplasia planned for elective colorectal resection at the hospital Medisch Spectrum Twente, with a veterans-specific activity questionnaire (VSQAQ) score ≤ 7 metabolic equivalents of task (METs) and who underwent a preoperative abdominal CT scan and preoperative CPET between February 2013 and May 2017 were included. The VSQAQ is a brief self-administered questionnaire to estimate aerobic fitness, in which a score ≤ 7 METs was used to preselect those patients with a low perceived aerobic fitness [17]. These formed the study data and were retrospectively analysed after this period. Ethical approval for the study protocol (registration number P13-18) was provided by the Medical Ethics Committee Twente (Dr J.F.F. Lekkerkerker, Clinical Pharmacologist, chairman) in September 2013, and written informed consent was obtained from each participant. Patients were excluded if the time higher VAT mass (odds ratio 1.02; $P = 0.036$) were associated with an increased risk of an AT ≤ 11.1 ml/kg/min.

Conclusion: Body composition variables from the preoperative CT scan were moderately associated with preoperative CPET-derived aerobic fitness. Higher ASA score and higher VAT mass were associated with an increased risk of an AT ≤ 11.1 ml/kg/min.

anaerobic threshold, cardiopulmonary exercise test, physical fitness, prehabilitation, preoperative risk assessment, skeletal muscle mass

What does this paper add to the literature?

Although cardiopulmonary exercise testing (CPET) is the gold standard test to assess aerobic fitness, it is not always available in clinical practice. From this study, it appears that the routinely performed preoperative abdominal computed tomography scan cannot replace CPET for preoperative risk assessment on aerobic fitness in colorectal surgery.
Computed tomography scan

A single slice of each patient’s routinely performed preoperative abdominal CT scan was selected at the level of the third lumbar vertebra (L3) on which both transverse processes were visible. CT scans were all screened for their quality. Patients with a CT scan of poor quality (e.g., large radiation artefacts, low dose) were excluded from analysis. Scans were analysed using sliceOmatic 5 (TomoVision) software for Microsoft Windows®. The cross-sectional areas (cm²) of skeletal muscle tissue, VAT and subcutaneous adipose tissue (SAT) were coloured automatically, and manually corrected if necessary, by two trained and blinded researchers (LvW and checked by DvD, both blinded for CPET analyses). Skeletal muscle tissue, VAT and SAT areas were normalized for the patient’s body height to calculate the L3 index (cm²/m²). The SM-RA was assessed by calculating the average Hounsfield units (HU) value of skeletal muscle mass. Low SM-RA is associated with increased intermyocellular and intramyocellular fat (myosteatosis) [18].

Cardiopulmonary exercise testing

As part of the study protocol, an incremental CPET was performed by patients preoperatively under controlled conditions at the lung function department, using a calibrated electronically braked cycle ergometer in upright position (Ergoline, Ergoselect 100). The following standardized pre-test instructions were given to the patients: (1) consume the last (light) meal at least 2 h before exercise testing, (2) adhere to usual use of medication and (3) wear comfortable sporting clothes and shoes. CPET comprised a 2-min resting phase to assess baseline cardiopulmonary values, followed by 3 min of unloaded cycling (warm-up), after which the work rate was progressively increased with constant increments of 5, 10 or 15 W/min, depending on the patient’s subjective physical fitness level and aimed at reaching a maximal effort within 8–12 min. Throughout CPET, patients had to maintain a pedalling frequency between 60 and 80 revolutions/min. The protocol continued until the patient’s pedalling frequency fell definitely <60 revolutions/min, despite strong verbal encouragement. After test termination, the patient completed a 5-min recovery phase of unloaded cycling (cool-down).

During CPET, patients breathed through a facemask (Hans Rudolph) connected to a Triple V volume transducer to calculate breath-by-breath minute ventilation, oxygen uptake (VO₂), carbon dioxide production (VCO₂) and the respiratory exchange ratio averaged at 10-s intervals (Oxycon Pro, Jaeger). Flow volume (3-L syringe) and gas calibration (ambient air and a gas mixture of 16% oxygen and 5% carbon dioxide) were performed manually before each test. Heart rate (HR), 12-lead electrocardiography, blood pressure and pulse oximetry were continuously monitored.

CPET data were interpreted by a trained and experienced clinical exercise physiologist (BB, blinded for CT scan analyses). The highest HR achieved during the CPET was defined as HR_peak. Data from other outcome variables were averaged over 30 s of exercise. VO₂peak Values were considered valid when at least one of the following criteria was met: an HR at peak exercise >95% of predicted (predicted peak HR [beats/min] = 208–0.7 × age [years]) or a respiratory exchange ratio at peak exercise >1.10. The AT was defined as the point at which the ventilatory equivalent for oxygen and the partial end-tidal oxygen tension reached a minimum and thereafter began to rise in a consistent manner, coinciding with an unchanged ventilatory equivalent for carbon dioxide and partial end-tidal carbon dioxide tension [19]. If this ventilatory equivalents method provided uncertain results, the V-slope method was used to estimate the AT (the point at which the linear slope of the relation between the VCO₂ and VO₂ changed) [20]. Finally, the oxygen uptake efficiency slope (OUES) which provides a valid objective effort-independent measure of aerobic fitness in elderly patients scheduled for major colorectal surgery was calculated [21]. Absolute VO₂peak, AT and OUES values were normalized for body mass as well.

Patient characteristics and outcome measures

Baseline patient characteristics included sex, age, body height, body mass, body mass index (BMI), smoking status, use of beta-blocker, METs score on the VSAQ, clinical signs of metastasis, American Society of Anesthesiologists (ASA) score (I–IV) and Charlson comorbidity index (divided into three groups: 0, 1 and 2+). Body composition and aerobic fitness outcomes were reported separately for men and women, as it is known that values significantly differ between sexes.

Statistical analysis

Data were analysed with the Statistical Package for the Social Sciences for Windows (version 23.0; IBM, SPSS Inc.). Continuous data were presented as mean and standard deviation or as median and interquartile range where appropriate. Categorical data were summarized by frequency and percentage. Pearson or Spearman correlation coefficients were calculated to examine univariable associations between continuous variables, depending upon the distribution of the variables. To investigate the univariable association between a continuous variable (e.g., AT) and a categorical variable, one-way ANOVA, the independent samples t test or the Mann–Whitney U test, as appropriate, was used. Univariable associations with a P < 0.10 were included in the multivariable analysis. For predicting continuous outcomes, linear regression analyses (method: enter) were performed to investigate the association between continuous CPET variables (dependent variable, e.g., AT) and preoperative independent variables.

A multivariable logistic regression analysis was performed to predict whether a patient had a relative AT ≤ 11.1 ml/kg/min. Preoperative variables were tested for their association with a relative
AT ≤ 11.1 ml/kg/min (P < 0.10), using the t test, Mann–Whitney U test, Fisher’s exact test or chi-squared test, as appropriate. A logistic regression model was performed to select which of the remaining variables were significant in a forward stepwise procedure (P in 0.10, P out 0.15). In the case of multicollinearity between variables, the variable that produced the best model fit (based on the –2 log likelihood) was included in the model. With the final selected significant variables, a new logistic regression model was made (method: enter) to utilize the maximum number of observations. Receiver operating characteristic (ROC) analysis was used to assess the independent ability of predictive variables to discriminate between patients with and without a relative AT ≤11.1 ml/kg/min; this AT cut-off was based on the work by West and others [8] in patients undergoing major colorectal surgery. The optimal cut-off point from the ROC analysis was based on our preference to have primarily a high sensitivity (with a reasonable specificity), as we aim to detect almost all high-risk patients that might benefit from a preoperative intervention (e.g., prehabilitation). A P < 0.05 was considered statistically significant.

RESULTS

Patients

Between February 2013 and May 2017, a total of 371 potential patients ≥60 years old with a colorectal tumour were assessed for eligibility. Of these patients, 189 (50.9%) had a VSAQ score ≤ 7 METs, of which 91 patients (48.1%) underwent a preoperative CPET.

Of these 91 patients, 13 patients were excluded: in two patients (2.2%) the AT and VO2peak could not be determined in two patients (2.2%) SM-RA could not be measured using their CT scan; in nine patients (9.9%) raw preoperative CPET data were not available; and in two patients (2.2%) the AT and VO2peak could not be determined due to a poor effort at the CPET (invalid test). Patient characteristics of the remaining 78 patients (45 men and 33 women, mean age 74.5 ± 6.4 SD years, range 61.5–90.3 years) are presented in Table 1.

All 78 patients performed the CPET without any complications or adverse events during or after the test. The AT was indeterminable in two (2.6%) patients, while they attained a valid VO2peak. Normalized for body mass, mean ± SD values of VO2peak and AT were 15.6 ± 3.7 ml/kg/min and 10.6 ± 1.9 ml/kg/min, respectively. Mean ± SD time between the CT scan and CPET was 15.2 ± 15.3 days. CPET results are shown in Table 2.

Mean ± SD skeletal muscle mass index was 50.9 ± 10.6 cm²/m² in men (range 31.1–91.5) and 36.6 ± 8.1 cm²/m² in women (range 20.4–66.7). CT scan measurements are depicted in Table 2.

Association between preoperative body composition parameters derived from the abdominal CT scan and preoperative CPET parameters

In the univariable analysis (Table 3), a Pearson correlation coefficient of 0.55 (P < 0.001) was found between the absolute AT and skeletal muscle mass index. Between the relative AT and skeletal muscle mass index, a correlation coefficient of 0.16 (P = 0.156) was observed. A Pearson correlation coefficient of 0.28 (P = 0.014) was found between the relative AT and SM-RA.

### Table 1: Patient characteristics

| Parameter                  | Total       |
|----------------------------|-------------|
| Age (years)                | 74.5 ± 6.4  |
| Sex (men)                  | 45 (57.7)   |
| Body height (cm)           | 169.9 ± 9.3 |
|   Men                      | 175.1 ± 7.1 |
|   Women                    | 163.0 ± 7.2 |
| Body mass (kg)             | 84.5 ± 14.3 |
|   Men                      | 89.0 ± 13.7 |
|   Women                    | 78.5 ± 12.9 |
| Body mass index (kg/m²)    | 29.2 ± 3.8  |
|   Men                      | 29.0 ± 3.8  |
|   Women                    | 29.5 ± 3.9  |
| Smoking                   | 11 (15.7)   |
| VSAQ score (METs)          | 5 ± 1       |
| Charlson comorbidity index |             |
|   0                        | 23 (29.5)   |
|   1                        | 27 (34.6)   |
|   ≥2                       | 28 (35.9)   |
| ASA score                  |             |
|   I and II                 | 61 (78.2)   |
|   III and IV               | 17 (21.8)   |
| Tumour localization        |             |
|   Ascending colon          | 29 (37.2)   |
|   Transverse colon         | 7 (9.0)     |
|   Descending colon         | 5 (6.4)     |
|   Sigmoid                  | 23 (29.5)   |
|   Rectum                   | 11 (14.1)   |
|   Other                    | 3 (3.8)     |
| Clinical metastasis category|             |
|   cM0                      | 67 (85.9)   |
|   cM1                      | 5 (6.4)     |
| Not applicable             | 6 (7.7)     |

Note: Values are presented as mean ± SD or as n (%). Abbreviations: ASA, American Society of Anesthesiologists; MET, metabolic equivalent of task; VSAQ, veterans-specific activity questionnaire.

aEight missing values.

bThirteen missing values.

cFour patients with a rectal tumour received neoadjuvant chemoradiation; one patient received neoadjuvant radiotherapy.

dTwo patients had a tumour in both the ascending and transverse colon; one patient had metachronous colorectal liver metastasis.

eIncludes dysplasia (n = 5) and metachronous colorectal liver metastasis (n = 1).
Variables with a $P < 0.10$ in the univariable analysis (age, body mass, body height, ASA, sex, skeletal muscle mass index and VAT mass) were included in a multivariable linear regression analysis to predict the absolute AT. BMI was also associated with absolute AT ($P < 0.10$) but was not included in the multivariable analysis because of multicollinearity between BMI, body mass and body height. In the final multivariable model ($R^2$ 51.1%), a lower age, a higher body mass, a lower ASA score and a higher skeletal muscle mass index were associated with a higher absolute AT (Table 4):

Absolute AT (ml/min) = 848.6 – (4.99 × age in years)
+ (4.18 × body mass in kg) – (124.4 × ASA score)
+ (4.65 × skeletal muscle mass index in cm²/m²)

For an ASA score of 1 or 2, a 1 must be used, whereas for an ASA score of 3 or 4 a 2 should be used in the equation.

Moreover, variables with a $P < 0.10$ in the univariable analysis (BMI, ASA, VSAQ score, SM-RA and VAT mass) were included in the multivariable linear regression analysis to predict the relative AT. Body mass was also associated with relative AT ($P < 0.10$) but was not included in the multivariable analysis because of multicollinearity between body mass and BMI. In the final multivariable model ($R^2$ 28.6%), a higher BMI, a higher ASA score and a lower SM-RA were associated with a lower relative AT (Table 4):

Relative AT (ml/kg/min) = 15.1 – (0.13 × BMI in kg/m²)
– (1.80 × ASA score) + (0.05 × SM-RA)

### TABLE 2 Preoperative body composition parameters derived from the abdominal CT scan and preoperative CPET parameters

| Parameter                              | Total (n = 78) | Men (n = 45) | Women (n = 33) | P value |
|----------------------------------------|---------------|-------------|---------------|---------|
| CT scan parameters                     |               |             |               |         |
| Skeletal muscle mass index (cm²/m²)    | 44.9 ± 11.9   | 50.9 ± 10.6 | 36.6 ± 8.1    | <0.001  |

| $WR_{peak}$ (W)                        | 98 ± 32       | 110 ± 32    | 83 ± 25       | <0.001  |
| $WR_{peak}$ (W/kg)                     | 1.2 ± 0.3     | 1.2 ± 0.3   | 1.1 ± 0.3     | 0.030   |
| $VO_{2peak}$ (ml/min)                  | 1312 ± 351    | 1413 ± 348  | 1173 ± 309    | 0.002   |
| $VO_{2peak}$ (ml/kg/min)               | 15.6 ± 3.7    | 16.0 ± 3.8  | 15.1 ± 3.5    | 0.262   |
| AT (ml/min)$^c$                        | 889 ± 181     | 937 ± 175   | 824 ± 171     | 0.006   |
| AT (ml/kg/min)$^d$                     | 10.6 ± 1.9    | 10.6 ± 1.9  | 10.5 ± 1.7    | 0.823   |
| $O_2$ pulse$_{peak}$ (ml/beat)$^e$    | 10.3 ± 2.6    | 11.2 ± 2.7  | 9.0 ± 2.0     | <0.001  |
| $O_2$ pulse$_{peak}$ (ml/kg/beat × 100)$^f$ | 12.3 ± 2.3 | 12.8 ± 2.6  | 11.7 ± 1.9    | 0.056   |
| VE/VCO₂ slope$^g$                      | 33.2 ± 6.6    | 33.8 ± 7.8  | 32.4 ± 4.6    | 0.375   |
| VE$_{peak}$ (l/min)                    | 56.6 ± 17.0   | 62.5 ± 16.7 | 48.7 ± 14.1   | <0.001  |
| VE$_{peak}$ (l/kg/min)                 | 0.7 ± 0.2     | 0.7 ± 0.2   | 0.6 ± 0.2     | 0.094   |
| OUES                                   | 1576 ± 444    | 1695 ± 428  | 1413 ± 418    | 0.005   |
| OUES/kg                                | 18.7 ± 4.5    | 19.2 ± 4.7  | 18.0 ± 4.2    | 0.248   |

Note: Values are presented as mean ± SD.

Abbreviations: AT, anaerobic threshold; CPET, cardiopulmonary exercise testing; $HR_{peak}$, heart rate at peak exercise; HU, Hounsfield units; $O_2$ pulse$_{peak}$, oxygen pulse at peak exercise; OUES, oxygen uptake efficiency slope; $RER_{peak}$, respiratory exchange ratio at peak exercise; SAT, subcutaneous adipose tissue; SM-RA, skeletal muscle radiation attenuation; VAT, visceral adipose tissue; VE/VCO₂ slope, minute ventilation to carbon dioxide production relationship; VE$_{peak}$, minute ventilation at peak exercise; $VO_{2peak}$, oxygen uptake at peak exercise; $WR_{peak}$, work rate at peak exercise.

$^a$Heart rate was invalid in eight patients (10.3%, six men and two women), so in this case $n = 70$.

$^b$A beta-blocker was used by 26 patients (17 men and nine women). 43 patients did not use a beta blocker, and in one patient beta blocker use was unknown.

$^c$The AT was not determinable in two patients (2.6%, one man and one woman), so in this case $n = 76$.

$^d$O₂ pulse values normalized for body mass are multiplied by 100 to increase readability.

$^e$The VE/VCO₂ slope was calculated using data up to the respiratory compensation point.

$^f$Independent samples t tests.
A multivariable logistic regression analysis was performed to investigate if a preoperative relative AT ≤ 11.1 ml/kg/min can be predicted from body composition variables derived from the abdominal CT scan and other patient characteristics. In the univariable analysis, age, body mass, BMI, VAT mass, ASA score, VSAQ score and Charlson score were associated with a relative AT ≤ 11.1 ml/kg/min (with a \( P < 0.10 \)) and were included in a forward stepwise multivariable analysis. A higher ASA score (OR 6.95, 95% CI 0.81–59.3, \( P = 0.076 \)) and a higher VAT mass (OR 1.01, 95% CI 1.00–1.03, \( P = 0.090 \)) were associated with an increased risk of a relative AT ≤ 11.1 ml/kg/min. Another logistic regression model was made (method: enter), with ASA and VAT mass, to include all patients (as, although ≤ 7 METs, the exact VSAQ scores of 13 patients were missing). In this final model, a higher ASA score (OR 5.64, 95% CI 1.15–27.7, \( P = 0.033 \)) and a higher VAT mass (OR 1.02, 95% CI 1.00–1.03, \( P = 0.036 \)) were associated with an increased risk of a relative AT ≤ 11.1 ml/kg/min. Patients with an ASA score of 3 or 4 were almost six times more likely to have a relative AT ≤ 11.1 ml/kg/min.

ROC analysis for predicting patients with a relative AT ≤ 11.1 ml/kg/min from ASA score and VAT mass gave an area under the curve (AUC) of 0.71 (95% CI 0.60–0.83, \( P = 0.002 \)) (Figure 1). Patients with a relative AT ≤ 11.1 ml/kg/min can be predicted with the formula \( 1 \times \text{exp}[-(0.74 + (0.02 \times \text{VAT mass}) + (1.73 \times \text{ASA})] \). For an ASA score of 1 or 2, a 0 must be used, whereas for an ASA score of 3 or 4 a 1 should be used in the equation. When choosing a cut-off point of 0.55, the sensitivity was 82.7% and specificity was 46.2%, while the positive predictive value was 75.4% and the negative predictive value was 57.1%.

## DISCUSSION

This study aimed to investigate the association between body composition variables derived from the preoperative abdominal CT scan and preoperative CPET variables of aerobic fitness in patients scheduled for colorectal surgery, to evaluate whether the preoperative CT scan can assist to preselect unfit patients. The results demonstrated that body composition variables were significantly associated with preoperative aerobic fitness, expressed as the absolute and relative AT, absolute and relative \( \text{VO}_{2\text{peak}} \), and OUES. In the multivariable regression model to predict the preoperative absolute AT, it was found that the absolute AT (R² 51.1%) was lower in patients with a lower skeletal muscle mass index, together with a higher age, a lower body mass and a higher ASA score. Variation in relative AT values (R² 28.6%) could be less well explained by body composition variables and other patient-related variables.

Body composition variables such as skeletal muscle mass correlate better with absolute measures of aerobic fitness (AT, \( \text{VO}_{2\text{peak}} \), and OUES) than with relative variables (here normalized for body mass) of aerobic fitness. This can be explained by the fact that skeletal muscle mass represents an absolute measure of the body's skeletal muscle mass, and a higher absolute skeletal muscle mass generally results in greater exercise-induced peripheral oxygen extraction and utilization by the exercising muscles, which is an important determinant for absolute aerobic fitness. Aerobic fitness refers to the maximal capacity of the pulmonary and cardiovascular system to take in and transport oxygen to the exercising muscles, and of those exercising muscles to extract and utilize oxygen from the blood for aerobic respiration [22]. Thus, aerobic fitness depends not merely on skeletal muscle mass and SM-RA, which might explain the weak-to-moderate correlation coefficients found in the current study. Findings of the current study are consistent with the
The current study also found that SM-RA was significantly correlated with relative AT and relative VO₂peak in the univariate analysis. Despite mounting evidence that prehabilitation has the potential to improve preoperative physical fitness and postoperative outcomes [28,29], there remains work to be done in order to develop an evidence-based approach that can identify patients who are at a higher risk of complications.

### Table 4
Multivariable linear regression analysis to predict the preoperative absolute and relative AT and absolute and relative VO₂peak

| CPET variable Parameter | B     | 95% CI       | P value |
|-------------------------|-------|--------------|---------|
| Absolute AT (ml/min)    |       |              |         |
| Age (years)             | -5.00 | -9.80-- -0.19| 0.042   |
| Body mass (kg)          | 4.18  | 1.69--6.66   | 0.001   |
| ASA score               | -124  | -199-- -49.8 | 0.001   |
| Skeletal muscle mass index (cm²/m²) | 4.65 | 1.69-7.62 | 0.003 |
| Relative AT (ml/kg/min) |       |              |         |
| Body mass index (kg/m²) | -0.13 | -0.23--0.03  | 0.014   |
| ASA score               | -1.80 | -2.70-- -0.90| < 0.001 |
| SM-RA (HU)              | 0.05  | -0.004--0.10 | 0.071   |
| Absolute VO₂peak (ml/min) | -12.0 | -21.3--2.63 | 0.013   |
| Age (years)             |       |              |         |
| Body height (cm)        | 12.5  | 5.34--19.7   | 0.001   |
| ASA score               | -270  | -413--128    | < 0.001 |
| Skeletal muscle mass index (cm²/m²) | 8.22 | 2.69-13.8  | 0.004  |
| Relative VO₂peak (ml/kg/min) | -0.14 | -0.24--0.04 | 0.008   |
| Age (years)             |       |              |         |
| Body mass index (kg/m²) | -0.42 | -0.59-- -0.25| < 0.001 |
| ASA score               | -2.40 | -4.11-- -0.69| 0.007   |
| Charlson comorbidity index | -1.12 | -1.98-- -0.26 | 0.012 |
| Skeletal muscle mass index (cm²/m²) | 0.09  | 0.03--0.15  | 0.003   |

Abbreviations: ASA, American Society of Anesthesiologists; AT, anaerobic threshold; BMI, body mass index; HU, Hounsfield units; SM-RA, skeletal muscle radiation attenuation; VO₂peak, oxygen uptake at peak exercise.

In a formula, absolute VO₂peak (ml/min) = 34.9 – (12.0 x age in years) + (12.5 x body height in cm) - (270 x ASA score) + (8.22 x skeletal muscle mass index in cm²/m²). For an ASA score 1 or 2, a 1 must be used, whereas for an ASA score 3 or 4 a 2 should be used in the equation.

In a formula, relative VO₂peak (ml/kg/min) = 38.4 – (0.14 x age in years) – (0.42 x BMI in kg/m²) – (2.40 x ASA score) – (1.12 x Charlson score) + (0.09 x skeletal muscle mass index in cm²/m²). For an ASA score 1 or 2, a 1 must be used, whereas for an ASA score 3 or 4 a 2 should be used in the equation.

Preoperative risk assessment is important, as it is the less physically fit patient that will benefit the most from prehabilitation [26,27].
risk assessment on aerobic fitness; however, it may contribute to the (pre)selection of unfit patients.

ETHICS STATEMENT
Ethical approval for the study protocol (registration number P13-18) was provided by the Medical Ethics Committee Twente (Dr J.F.F. Lekkerkerker, clinical pharmacologist, chairman) in September 2013.

PATIENT CONSENT STATEMENT
Written informed consent was obtained from each participant.

CONFLICT OF INTERESTS
All authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

AUTHOR CONTRIBUTIONS
