Abstract: There have been many studies on the effect of durability and compressive strength on the increase of the mixing rate of admixtures. However, there is no research that can provide a guide on the optimal mixture proportions for maintaining compressive strength and secure durability properties when using local materials. Therefore, the purpose of this article is to assess the durability and engineering performances of concrete based on local fly ash (FA), as well as to derive the optimum CaO content scope for ensuring durability. The results of this study were compared with the results of the previous study of high-volume ground-granulated blast-furnace slag (GGBFS) concrete. To achieve this, tests were carried out by increasing the admixture mixing rate in 10% increments from 0% to 70%. The unit water was set at 175 kg/m³ and the amount of binder was set at 330 kg/m³. It was found that the overall compressive strength of the hardened concrete decreased when the admixture mixing rate increased. In addition, the compressive strength of specimens tended to improve as all the CaO contents of the admixture types increased. When the durability properties were examined, it was found that the relative dynamic elasticity modulus and carbonation depth decreased, and the chloride penetration depth increased as the CaO content increased for both GGBFS and FA. The weight loss rate, however, remained similar. Based on the results of this study, the optimal CaO content that achieved satisfactory engineering and durability properties was found to be between 39% and 48% for FA. The results of this study will be able to offer guidelines for the mixture rates of FA when mixing durable concrete for use in the field. Additionally, these results are expected to be utilized as a basis for determining instructions relating to chemical composition in order to develop binders with improved durability.

Keywords: durability properties; ordinary Portland cement (OPC); ground-granulated blast-furnace slag (GGBFS); fly ash (FA)

1. Introduction

The new global standards in relation to engineering have resulted in the development of recycled building materials, as an increased amount of energy-saving and eco-friendly infrastructure is required [1,2]. Traditional concrete, the most frequently used building material worldwide, is known to result in severe environmental pollution because it uses both energy and raw materials in large quantities [3,4]. Therefore, research on methods to minimize its negative impact on the environment is...
essential. For this reason, ground-granulated blast-furnace slag (GGBFS) and fly ash (FA), which are industrial byproducts, have been extensively used as substitutes of ordinary Portland cement (OPC), and many related studies have been conducted on this subject [5–7]. GGBFS and FA act not only as alkali-activated materials (AAMs), but also as supplementary cementitious materials (SCMs) [8]. If admixtures are used as SCMs, they can improve the durability, long-term strength, and constructability of the fabricated concrete [9,10]. Geopolymers are a representative example of an admixture that may be used as an AAM. Xie et al. [11] experimentally verified that GGBFS- and FA-based geopolymers can provide the excellent sulfuric acid resistance of recycled concrete. AAMs, however, are not yet used in the field due to their fast setting time, large shrinkage, and high unit price. Therefore, an in-depth study on the usability of SCMs is required to improve their construction site applicability.

GGBFS is an industrial by-product, generated when producing pig iron. It turns into a granular and amorphous fine powder through quenching and grinding. GGBFS is mainly composed of SiO$_2$, Al$_2$O$_3$, CaO, and MgO. Therefore, it can be called aluminosilicate, which uses CaO and MgO as its base components [12–14]. When in contact with water, GGBFS slowly undergoes a hydration reaction, and the reaction rate increases as the pH value is increased [10,15]. Khatib et al. [16] conducted an experiment by replacing up to 80% of cement with GGBFS and reported that compressive strengths equivalent to that of OPC concrete were obtained when the mixing rate was 60% or less. In particular, they verified that GGBFS is effective in improving the long-term strength of concrete by confirming that the compressive strength was increased after 28 days of aging. In addition, Parron-Rubio et al. [17] found that the specimens for which cement was replaced with GGBFS exhibited 10% higher compressive strength than the plain specimen after 90 days of aging. They also reported that the specimens with GGBFS showed similar or higher compressive strengths than the conventional concrete after seven days of aging.

Moreover, the durability of 100% OPC concrete could be improved by using GGBFS as an SCM [18]. The improvement of durable concrete is an important issue in relation to the extension of the service lives of concrete structures. It was verified that the use of GGBFS can improve the microstructures of concrete by adding a C-S-H phase, and it is effective in reducing the conductivity of chloride due to its provision of an increased alumina content [19]. Jang et al. [20] conducted a 180-day immersion test with a 30% CaCl$_2$ solution and reported that the system with GGBFS and MgO endured damage far more effectively. Cheng et al. [21] claimed that the partial substitution of cement with GGBFS had a significant effect on the total flexural stiffness, corrosion rate, and permeability of a fabricated concrete beam.

FA is a byproduct of coal-fired power generation and can be used as an SCM in concrete [22]. Van Nguyen et al. [23] experimentally verified that the long-term compressive strength of concrete mixed with FA increases due to the continuous hydration process, even though its compressive strength decreases initially. They also reported that FA increases the sulfuric acid resistance of concrete but has a limited effect on reducing the corrosion potential of the steel reinforcement structures in concrete. According to Thomas et al. [24], the focus on the use of FA in concrete has shifted towards quantifying the benefits for boosting the sustainability of concrete. Moreover, Papadakis et al. [25] reported that the substitution of FA in an appropriate proportion can improve the chlorine resistance as well as the compressive strength of concrete.

As mentioned above, an increase in the admixture mixing rate generally improves the durability of concrete under the same mixing conditions, but decreases the compressive strength. There is, however, currently no study that presents guidelines for optimum mixing rates that can address compressive strength degradation and ensure durability using local GGBFS and FA materials in the actual field. There are also no practical data that can be used as a basis for determining the chemical compositions required to develop GGBFS- and FA-based binders with excellent durability. However, in a previous study, Lee [26] evaluated engineering performance and durability according to the CaO content rates of concrete mixed with high-volume GGBFS produced in a local area. The optimum range of CaO
content was derived, which can secure durability. Therefore, studies related to concrete based on high-volume FA are urgently required.

In this article, the durability properties and engineering performance of binary mixed concrete with locally produced FA were evaluated to derive the optimum CaO content, to obtain concrete with remarkable durability for use in standard construction applications. In addition, by comparing the results of this study with those of previous studies, we intend to enhance its applicability for construction sites.

2. Experimental Procedure

2.1. Materials

Table 1 shows the chemical composition rate of the binders used. OPC showed the highest CaO content at 60.20%, whereas FA showed the highest SiO₂ content at 57.90%. This result was derived from X-ray fluorescence, using Axios PW 4400 equipment (Malvern Panalytical, Seongnam-si, Korea). In addition, the second highest constituents of OPC and FA were SiO₂ and Al₂O₃, respectively, indicating that the chemical composition of the two materials was significantly different. Table 2 summarizes the physical characteristics of OPC, FA, aggregate, and chemical admixture used in this study. The OPC type 1 was used according to KS L 5201 [27], and in the case of FA, type 2 was used according to KS L 5405 [28]. As fine aggregates, crushed sand and washed sea sand were blended at a weight rate of 60:40, respectively. In addition, crushed granitic aggregate was applied for coarse aggregate, and polycarboxylate superplasticizer (widely used in the field) was applied for the liquid admixture. The density and fineness of OPC and FA were calculated according to ASTM C188 [29] and ASTM C204 [30], respectively. The density and absorption of aggregates were calculated based on ASTM C127 [31], whereas the fineness modulus (FM) was calculated based on ASTM C136 [32].

2.2. Experimental Processes

Table 3 shows the experimental design used in this study. The unit binder was set at 330 kg/m³, and the unit water was fixed at 175 kg/m³ according to the most commonly used mixing ratio standards in the local field. The test was carried out under the condition that the temperature was kept constant at 20 °C. The rate of the admixture changed between 0% and 70% using increments of 10%. The test parameters of this study consisted of 13 items, and were used to evaluate raw material properties, engineering properties, and durability properties. Table 4 shows the concrete mix table, and the mix ID is divided into 8 types, from Plain to F70. The water/binder ratio was fixed at 0.53. The standard of ready-mixed concrete was 25-24-180, which is most commonly used in the general field.

2.3. Testing Methods

Table 5 shows the testing methods used in terms of the items evaluated in this study. The results of all tests were calculated as the average value for three specimens. In evaluation parameter 1, for the raw material properties, the article size distribution and grading distribution were measured according to the standards of ASTM C204 [30] and ASTM C136 [32]. Furthermore, X-ray fluorescence (XRF), X-ray diffraction (XRD), and scanning electron microscopy (SEM) were used for microstructure

analysis, and tests were performed according to the standards of ASTM C114 [33] and ASTM C457 [34], and ASTM C1723 [35], respectively. In evaluation parameter 2, slump and air volume tests were conducted based on ASTM C143 [36] and ASTM C231 [37]. For the compressive strength test, ASTM C873 [38] and ASTM C39 [39] were referenced. Compressive strength specimens were fabricated at a columnar mold (size: Ø 100 × 200 mm) for these tests.

Table 5. Testing methods for the assessed parameters.

| Assessed Parameter                  | Testing Method       | Geometry                  |
|-------------------------------------|----------------------|---------------------------|
|■ Raw material properties            |                      |                           |
| - Particle size distribution and grading distribution (%) | ASTM C204 and ASTM C136 | -                         |
| - X-ray fluorescence and X-ray diffraction | ASTM C114 and ASTM C457 | -                         |
| - Scanning electron microscope      | ASTM C457            | -                         |
|■ Engineering properties             |                      |                           |
| - Slump (mm) and air content (%)    | ASTM C143 and ASTM C231 | Ø 100 × 200 mm            |
| - Compressive strength (MPa)        | ASTM C873, ASTM C39  | Ø 100 × 200 mm            |
|■ Durability properties              |                      |                           |
| - Chloride penetration depth and carbonation depth (mm) | KS F 2584 and NT Build 492 | Ø 100 × 200 mm, Ø 100 × 50 mm |
| - Relative dynamic elasticity modulus and weight loss rate (%) | ASTM C666 | 100 × 100 × 400 mm |

In evaluation parameter 3, for checking the chloride penetration and carbonation depth, KS F 2584 (columnar specimen size: Ø 100 × 200 mm) [40] and NT Build 492 (columnar specimen size: Ø 100 × 50 mm) [41] were used as the test standardization. In addition, the test for the relative dynamic elasticity modulus and weight loss rate were conducted according to ASTM C666 (cubic specimen size: 100 × 100 × 400 mm) [42]. For this test, a specimen was prepared and standard curing was performed until the age of 28 days, and then an accelerated carbonization test was performed. At this time, the accelerated carbonation was set under the conditions of 10% CO₂ concentration, 60% ± 3% relative humidity, and 20 °C ± 1 °C temperature. The carbonation depth was measured by spraying a 1% phenolphthalein solution at the age of 4 and 8 weeks. In addition, 0.5 M NaCl solution was used as a negative electrode cell solution and a saturated Ca(OH)₂ solution was used as a positive electrode cell solution in order to test the chlorine ion penetration resistance according to the potential difference.

3. Experimental Test Results

3.1. Raw Material Properties

The particle size distributions of OPC and FA are showed in Figure 1, and are compared with the results of GGBFS obtained by Lee [26]. The mean sizes and fineness moduli of OPC, GGBFS, and FA were measured to be 19.46 µm and 1.18, 22.47 µm and 1.08, and 21.30 µm and 1.23, respectively. As shown in Figure 2, to compare the shape of the grain of the OPC, GGBFS, and FA powders, SEM analysis was conducted using a Genesis-2020 (Emcrafts, Gwangju-si, Korea). It was observed that OPC and GGBFS similarly appeared as ellipsoidal polyhedrons when their particles were larger than 10 µm and as atypical crystals when the particles were smaller than 10 µm, through SEM imaging. In the case of FA, however, a spherical shape and atypical crystals were observed.

In addition, for analyzing the grading of the coarse and fine aggregates, sieve analysis was carried out. The analysis results satisfied all the cumulative passing criteria based on ASTM C136 [33] according to the sieve opening size for the fine and coarse aggregates, as shown in Figure 3. The FM of the mixed fine aggregate was found to be 2.84, whereas that of the coarse aggregate was found to be 6.94. In order to know the types of crystalline substances contained in particles by binder types used, X’pert3 Powder PW 3050 equipment (Malvern Panalytical, Seongnam-si, Korea) was used to analyze the XRD patterns and the result is shown in Figure 4. It was found that OPC was primarily composed of 3CaO·SiO₂ (C₃S), 2CaO·SiO₂ (C₂S), 3CaO·Al₂O₃ (C₃A), and 4CaO·Al₂O₃·Fe₂O₃ (C₄AF) minerals. In addition,
GBFS was formed of akermanite (2CaO·MgO·2SiO₂) and gehlenite (2CaO·Al₂O₃·SiO₂) minerals. Li et al. [43] reported that GGBFS contains a mixture of depolymerized calcium aluminosilicate glass in addition to the two minerals. On the other hand, FA was composed of mullite and quartz minerals.

Figure 1. The particle size distributions of OPC and FA compared with ground-granulated blast-furnace slag (GGBFS) by Lee, adapted from [26].

![Particle size distributions of OPC and FA compared with GGBFS.](image)

**Figure 1.** The particle size distributions of OPC and FA compared with ground-granulated blast-furnace slag (GGBFS) by Lee, adapted from [26].

![Scanning electron microscope images.](image)
...whereas the air contents were 4.1%~5.3% and 4.6%~5.7%, respectively. Within the standards of 4.5% ± 1.5% for all mixing proportions. Under the same mixing conditions, both the slump and air content of FA were found to have lower properties than those of GGBFS. In this study, to examine the influences of the admixture type and mixing rate on workability, the water content required to guarantee the target slump range of 180 ± 25 mm was measured after fixing the unit binder content and chemical admixture content at 330 and 2.31 kg/m³, respectively. As shown in Figure 6, it was found that the unit water content decreased by approximately 2.75 kg/m³ for FA as the admixture mixing rate increased by 10%. This indicates that workability can be improved through the substitution of the admixtures under the same unit binder content.

3.2. Engineering Properties

Figure 5 shows the measured values of slump and air content of OPC and FA compared with GGBFS as measured by Lee [26] for fresh concrete by the admixture mixing rate. The slumps of GGBFS and FA were 165~205 mm and 195~205 mm, whereas the air contents were 4.1%~5.3% and 4.6%~5.7%, respectively. Therefore, the slump was suitable for the target value of 180 ± 25 mm, and the air content also was within the standards of 4.5% ± 1.5% for all mixing proportions. Under the same mixing conditions, both the slump and air content of FA were found to have lower properties than those of GGBFS. In this study, to examine the influences of the admixture type and mixing rate on workability, the water content required to guarantee the target slump range of 180 ± 25 mm was measured after fixing the unit binder content and chemical admixture content at 330 and 2.31 kg/m³, respectively. As shown in Figure 6, it was found that the unit water content decreased by approximately 2.75 kg/m³ for GGBFS and 3.00 kg/m³ for FA as the admixture mixing rate increased by 10%. This indicates that workability can be improved through the substitution of the admixtures under the same unit binder content.
conditions, and that FA demonstrates a higher workability improvement effect than GGBFS at the same mixing rate.

![Figure 5](image-url)  
**Figure 5.** Results of the air content and slump values of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.

![Figure 6](image-url)  
**Figure 6.** Results of the unit water content of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.

Figure 7 shows the compressive strength of OPC and FA compared with GGBFS by Lee [26] at different ages for each admixture mixing rate. Overall, FA exhibited less compressive strength development with aging than GGBFS. At 3 and 7 days of aging, the GGBFS and FA specimens began to show a difference in compressive strengths when the admixture mixing rate was 40%. At 28 and 56 days of age, conversely, a difference in these compressive strengths occurred when the admixture mixing rates were 10% and 30%, respectively. To examine the compressive strength development rate with aging, the compressive strength rate—compressive strength of FA/compressive strength of GGBFS—was calculated according to the admixture mixing rate, as shown in Figure 8. The result showed a tendency to decrease along the curve of a quadratic equation as the admixture mixing rate increased, even though the error range increased.

Figure 9 shows that the compressive strength tended to slightly decrease, except at 28 days of aging, as the GGBFS mixing rate increased. FA exhibited larger decrements in compressive strength than GGBFS at all ages. To examine the long-term strength development rate of each admixture after 28 days of aging, an analysis was conducted, as shown in Figure 10. Both GGBFS and FA exhibited high long-term strength development rates as the mixing rate exceeded 15%. In particular, the development
The development rate of GGBFS was higher than that of FA, indicating that GGBFS has a higher strength improvement effect after 28 days than FA at the same mixing rate.

**Figure 7.** Results of the compressive strength of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) by age.

**Figure 8.** Result of compressive strength (FA)/compressive strength (GGBFS) as measured by Lee (adapted from [26]) in terms of the mixing rate.

**Figure 9.** Results of the compressive strength of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.
The results showed a tendency to decrease as the mixing rate increased. The rate of the highest and the lowest value was 442.1% for GGBFS and 153.3% for FA, indicating that the substitution of FA has a lower carbonation resistance than GGBFS at the same mixing rate. It is necessary to further examine the appropriate mixing rates for each admixture type in terms of the carbonation development after 28 days. At an age of eight weeks, the carbonation depth of GGBFS grew up to about 161.7% in comparison with the lowest value, 70% mixing rate. In addition, the carbonation depth of FA increased to approximately 379.0% under the same conditions. FA exhibited a relatively higher carbonation depth than GGBFS at the same mixing rate, confirming that FA has a lower carbonation resistance than GGBFS at the same mixing rate.

![Figure 10](image-url)  
**Figure 10.** Results of compressive strength (56 days)/compressive strength (28 days) of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.

### 3.3. Durability Properties

Figure 11 shows the measured values of carbonation depth of OPC and FA compared with GGBFS as measured by Lee [26], according to the mixing rate. The carbonation depth also tended to increase as the admixture mixing rate increased. At an age of eight weeks, the carbonation depth of GGBFS grew up to about 161.7% in comparison with the lowest value, 70% mixing rate. In addition, the carbonation depth of FA increased to approximately 379.0% under the same conditions. FA exhibited a relatively higher carbonation depth than GGBFS at the same mixing rate, confirming that FA has a lower carbonation resistance than GGBFS at the same mixing rate.

![Figure 11](image-url)  
**Figure 11.** Results of the carbonation depth of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.

Figure 12 shows the measured values of chloride penetration depth by the admixture mixing rate. The results showed a tendency to decrease as the mixing rate increased. The rate of the highest and the lowest value was 442.1% for GGBFS and 153.3% for FA, indicating that the substitution of GGBFS is more beneficial than that of FA in terms of a resistance towards chloride. It is necessary to further examine the appropriate mixing rates for each admixture type in terms of the carbonation depth and chloride penetration depth for their application in the field.

Tests for weight reduction rates and relative dynamic elasticity modulus were performed to evaluate the influences of the admixture mixing rate on freeze-thawing and different chemical attacks.

Figure 13 shows the relative dynamic elasticity modulus of OPC and FA compared with GGBFS as measured by Lee [26], according to the mixing rate. As the admixture mixing rate increased, the relative...
dynamic elasticity modulus tended to go up. Under the same mixing conditions, FA more rapidly increased towards 100% than GGBFS and exhibited higher relative dynamic elasticity modulus values.

Figure 12. Results of the chloride penetration depth of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.

Figure 13. Results of the relative dynamic elasticity modulus of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.

To review the influences of the admixture mixing rate on the specimens’ surface degradation, the weight loss rate was measured by the admixture mixing rate, as shown in Figure 14. The FA and GGBFS specimens reached 100% or higher when the mixing rate exceeded 5% and 15%, respectively. This indicates that it is necessary to design the mixing proportions reflecting the weight reduction rate and relative dynamic elasticity modulus for application in construction sites.

Figure 14. Results of the weight loss rate of OPC and FA compared with GGBFS as measured by Lee (adapted from [26]) in terms of the mixing rate.
4. Discussions

4.1. Engineering Properties Determined via Chemical Composition

Figure 15 shows the measured values of CaO content and CaO/SO$_3$ rate in terms of the admixture mixing rate. As the mixing rate increased, the CaO content and CaO/SO$_3$ rate of GGBFS decreased to 82.2% and 90.2%, respectively. In the case of FA, conversely, the CaO content decreased to 34.7% and the CaO/SO$_3$ rate increased to 110.9%. Moreover, the representative chemical components (SO$_3$, CaO, and Fe$_2$O$_3$) tended to decrease, whereas CaO, Fe$_2$O$_3$, and SO$_3$ increased as the mixing rate of GGBFS increased. For FA, SiO$_2$, Al$_2$O$_3$, and Fe$_2$O$_3$ increased, whereas CaO, MgO, and SO$_3$ decreased.

Figure 15. Results of the CaO content and CaO/SO$_3$ rate in terms of the mixing rate.

Figure 16 shows the measured values of CaO/SiO$_2$ and SiO$_2$/Al$_2$O$_3$ molar rates according to the admixture mixing rate. As the GGBFS mixing rate increased, both the CaO/SiO$_2$ and SiO$_2$/Al$_2$O$_3$ molar rates decreased. In the case of FA, however, the CaO/SiO$_2$ molar rate increased and the SiO$_2$/Al$_2$O$_3$ molar rate decreased. When regression analysis was conducted using the triangular graph of the CaO/SiO$_2$ and SiO$_2$/Al$_2$O$_3$ molar rates, it was confirmed that GGBFS is more beneficial in terms of long-age strength and less beneficial in terms of rapid hardening compared to FA.

Figure 16. CaO/SiO$_2$ and SiO$_2$/Al$_2$O$_3$ molar rates in terms of the mixing rate.

Figure 17a shows the compressive strength of the fabricated specimens by the CaO content. As the unit CaO weight went up, the compressive strength also tended to increase. When the CaO content was between 49.49% and 58.67%, however, the compressive strength of GGBFS was lower than that of FA at ages of 3 and 7 days. This appears to be because GGBFS is less beneficial in terms of rapid hardening.
compared to FA, as indicated in the results of Figure 16. Figure 17b shows the compressive strength development rate of each admixture by age. As the CaO content increased, the compressive strength development rate tended to slightly decrease. In the case of the GGBFS specimens, in particular, the strength development rate was higher for strengths at the early ages.

![Figure 17](image1.jpg)

**Figure 17.** Results of the (a) compressive strength and (b) compressive strength development rate according to the varied CaO content.

Figure 18 shows the compressive strength of each admixture type by the CaO/SO₃ rate. As the CaO/SO₃ rate increased, the compressive strength of the GGBFS specimens showed a tendency to increase except at 56 days of age, whereas that of the FA specimens showed a tendency to decrease at all ages.

![Figure 18](image2.jpg)

**Figure 18.** Results of the compressive strength in terms of the CaO/SO₃ rate.

4.2. Derivation of an Optimum CaO Content Range

Figure 19 shows the optimum CaO content range for ensuring an adequate durability performance, which was derived for FA by considering all of the contents mentioned above. For concrete replaced with FA to ensure an adequate durability properties, it is desirable to reduce the carbonation and chloride penetration depth while maximizing the relative dynamic elasticity modulus and weight reduction rate when mixing concrete.

As can be seen from Figure 19, the optimum CaO content of FA was found to be between 39% and 48%. This corresponds to a FA mixing ratio range between 21.7% and 37.7%. In this range, the compressive strength value at the age of 28 days was found to be between 25.1 and 31.0 MPa, which exceeded the target compressive strength ($f_{ck} = 24$ MPa). For reference, according to a previous
study by Lee [26], the optimum CaO content of GGBFS used to satisfy all of the four durability test conditions was found to be between 53% and 56%. This corresponds to a GGBFS mixing rate range between 27.5% and 47.1%. Therefore, the optimum mixing rate of FA was evaluated to be slightly lower than that of GGBFS.

Figure 19. Optimum CaO content range of FA for ensuring adequate durability performance.

5. Conclusions

In this article, the engineering performance and durability properties of binary blended concrete containing a large amount of fly ash (FA) were evaluated, and the optimum CaO content range to ensure adequate durability was deduced by each admixture type. In addition, the results of this study and the results of a previous study by Lee [25,27] on high-volume GGBFS concrete were compared with each other on the basis of various properties. The conclusions of this article are as follows:

1. When the unit content of water required to ensure the target slump range of 180 ± 25 mm was measured after fixing the unit binder content and chemical admixture content in fresh concrete, it was found that the unit water content decreased by 3.00 kg/m³ in the case of FA (approximately 2.75 kg/m³ for GGBFS) as the admixture mixing rate increased by 10%.

2. In hardened concrete, the compressive strength decreased when the admixture mixing rate increased, and FA more significantly reduced the compressive strength than GGBFS. In addition, it was found that both GGBFS and FA increased the compressive strength development rate after 28 days of aging when the admixture mixing rate exceeded 15%.

3. The overall compressive strength increased as the CaO content increased, regardless of the admixture type. When the CaO content was between 49.49% and 58.67%, however, the compressive strength of GGBFS was lower than that of FA at ages of 3 and 7 days. The GGBFS specimens exhibited higher compressive strength development rates at the early ages.

4. When the durability properties were examined, it was found that the depth of carbonation and relative dynamic elasticity modulus decreased, whereas the depth of chloride penetration tended to increase as the CaO content increased for both GGBFS and FA. The weight loss rate, however, was relatively unchanged.

5. The optimum CaO content satisfying all of the desired engineering and durability properties required in this study was found to be between 39% and 48% for FA (i.e., an FA mixing rate of 21.7% to 37.7%). Therefore, the optimum CaO content of FA was found to be slightly lower than the results of the previous study (i.e., between 53% and 56% for GGBFS).

The engineering and durability property evaluation data comparing FA and GGBFS derived in this study and the optimum CaO content ranges derived to secure durability will be able to provide guidelines for mixing proportions when applying high-volume FA-based concrete in local construction fields in future projects. They are also anticipated to be utilized as a basis for determining chemical composition standards for developing binders to improve the durability of the fabricated concrete.
Author Contributions: J.L., T.L., and H.C. equally contributed to the research conceptualization and all investigations performed under its purview. Resource procurement was handled by J.L. and T.L. The original draft of the manuscript was prepared by J.L. and T.L., whereas the final draft was reviewed and edited by J.L., T.L., D.-E.L., and H.C. All authors have read and agreed to the published version of the manuscript.

Funding: This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. NRF-2018R1A5A1025137).

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the results.
