INTRODUCTION

One of the most common malignancies in the world is oral cancer. It is more common in South East Asia due to the prevalence of oral habits such as betel nut chewing, smoking, alcohol consumption. Apart from these factors, there are other various etiological factors that cause oral cancer.\(^1\) The two main factors which influence cancer are genetic and epigenetic. The incidence of oral cancer in young adults ranges from 0.4% to 5.5%. The absence of significant habits has led many people to consider other factors such as diet, immune deficiency, genetic factors, certain viruses such as herpes simplex virus, human papillomavirus in the etiopathogenesis of oral cancer.\(^2,3\)

It has also been cited in earlier literature that oral cancer develops sometimes with no associated risk factors.\(^4\) Genetic predisposition has been shown to be an etiological factor for OSCC. In a study done by Cooper et al., 31 of 105 Head and neck cancer patients had relatives that developed oral cancer.\(^5\) It is believed that certain individuals inherit the susceptibility to metabolize carcinogens and pro-carcinogens and have impaired ability to repair DNA damage.\(^6\)

The use of mouthwash is also known to have been an etiological factor as they usually contain alcohol as a solvent or as preservative.\(^7\) Viral infections caused by EBV, HPV, and herpes simplex virus are considered an important etiological factor. Oral hairy leukoplakia and lymphoproliferative disease in immunosuppressed patients is caused by EBV. HPVs are the most common group of viruses implicated in oral carcinogenesis. These cause benign proliferative lesions such as papillomas, condyloma accuminatum, verruca vulgaris, and Heck’s disease. HPV, most commonly found in genital cancers has also been found commonly in oral cancers.\(^8,9\) Fungal infections such as those caused by Candida species, most importantly, Candida albicans has been implicated in the pathogenesis of oral premalignant lesions. Various clinical trials, surveys, and reviews have been carried out by our team. Now, we are focusing on epidemiological studies. The
The purpose of this study is to assess the occurrence of oral cancer in patients without any habits.

**MATERIALS AND METHODS**

**Study Setting**
This retrospective study was based on data collected from the patient records of a Private Dental College and Hospitals. Records of patients who reported between the months of June 2019 to March 2020 were reviewed. Approval was obtained from the Institutional Scientific Review Board. Two examiners were included in the study. The ethical approval number for the study is SDC/SIHEC/2020/DIASDATA/0619-0320.

**Sampling**
Cross verification of data for error was done by additional reviewers and by photographic evaluation. Simple random sampling was done to minimize sampling bias. After reviewing, the case sheets were filtered based on data required. The final sample size was 50 patients with oral cancer. The inclusion criteria were patients with oral cancer. The exclusion criteria were patients without oral cancer, patients with premalignant conditions, and patients whose case records were incomplete.

**Data collection**
The data was entered in the system in a methodical manner. The data was entered in excel manually and imported to SPSS for analysis.

**Analytics**
IBM SPSS Software [Version 19: IBM corporation NY USA] was used for data analysis. Descriptive statistics which included frequency of distribution was used for the statistical analysis. The independent variables were age and gender. Chi-square test was performed. The level of significance was set at 0.05.

**RESULTS AND DISCUSSION**
The data was imported to SPSS version 19 and the results were obtained using Chi-square test. In this study, it was found that about 8% of the patients had oral cancer without any association with adverse oral habits (Figure 1). The habits that were present were smoking, gutka consumption, and paan chewing. It was also found that oral cancer in patients not having any habits was predominant in females, which accounted for 6% of cases. The occurrence of oral cancer in male patients without any habits was found to be 2% (Figure 2).
Oral cancer prevalence is high in developing countries and is the most common cancer in India. Oral cancer is observed as a multifactorial disease in which environmental, genetic, and epigenetic factors play a major role. Oral squamous cell carcinoma (OSCC) is rare in young patients and is most found in patients during the 6th and 7th decade of life, primarily occurring in males. Case-control studies have shown that smoking and/or alcohol is the major risk factor for oral cancer. In India, because of cultural, ethnic, geographic factors, and the popularity of addictive habits, the frequency of oral cancer is high.

Many studies state that the prevalence of habits in males is more than in females and because of this it has been observed that men face twice the risk of oral cancer when compared to females. In our study oral cancer in patients not having any habits was found to be 8%. In a study conducted by Malovvala et al., it was found that 15% of the population studied had no oral habits which are in accordance with the present study. Similar results have been obtained by Shah et al. It has been observed that 2% of the population studied had mucosal changes without the presence of oral habits in a study conducted by Patil et al. A hospital-based 10-year retrospective study from Karnataka, reported that 25% of the patients diagnosed with oral cancer were habit-free, which is significantly more compared to the present study.

The habits that were most commonly present in patients in our study include pan chewing, gutka, alcoholism, and smoking. It has been studied by Sankaranarayanan et al. that factors other than tobacco and alcohol are involved in the etiology of the oral tongue cancers and cancer in other intra-oral sites excluding buccal mucosa in young patients. It has been observed that mouthwash containing alcohol increased the risk of oral cancer in patients who neither smokes nor consumes alcohol, though the results were statistically not significant in a study conducted by Winn et al. The traditional risk factors of oral cancer have been extended to include other factors such as iron deficiency anemia, chronic candidiasis, and herpetic infections. In a study done by Chang et al., it was found that HPV-associated oral cancer was significantly higher in patients without the presence of habits.

Elevated fasting glucose level and estrogen deficiency have been observed to be a strong risk factor of oral cancer in females, especially in the cancer of the gingiva in a study conducted by Suba et al. A positive association was found between non-vegetarian diet, poor oral hygiene, poor dentition, and the development of oral cancer.

Though the present study is in accordance with previous literature, the limitations faced in the study were smaller sample sizes and the results cannot be extrapolated to a larger population because of geographical limitations.

**CONCLUSION**

Within the limitations of the study, it was found that the number of patients diagnosed with oral cancer without any habits was comparatively less than those with adverse habits. Future studies on various other etiologies causing oral cancer and the etiopathogenesis should be studied, which will aid in the early diagnosis of oral cancer.

**ACKNOWLEDGEMENTS**

This study was supported by the Institution by providing insights and expertise that greatly assisted the study. We would also like to thank the reviewers of the article for the valuable insights provided by them.

**Conflict of Interest:** There was no conflict of interest.

**Funding Information:** The author confirmed that there is no funding support.
