We study the graphite intercalated compound CaC$_6$ by means of Eliashberg theory. We perform an analysis of the electron-phonon coupling and define a minimal 6-band anisotropic structure, that leads to a Fermi surface dependence of the superconducting gap. A comparison of the superconducting gap structure obtained using the Eliashberg and the superconducting density functional theory is performed. We further report the anisotropic properties of the electronic spectral function, the polaronic quasi-particle branches and their interplay with Bogoljubov excitations.

The electron-phonon interaction leads to many significant physical phenomena in solids (notably, superconductivity), and has therefore been studied extensively both in model systems and in real materials. One important aspect of this kind of interaction is the formation of a coupled electron-phonon system with new interesting features such as the appearance of polaronic sub-bands branching from the main electronic bands. This low energy features of the electronic structure can be observed thanks to the recent developments in the resolution of Angle-Resolved Photo Emission Spectroscopy (ARPES).

The theoretical background to deal with metallic polarons has been laid down by Engelsberg and Schrieffer (ES). For this they used a field theoretical approach combined with Einstein-Debye model to mimic the phonon spectrum. The ES theory shows the damping of electrons by phonons and the development of branches in the electronic dispersion corresponding to energy and strength of the phonon modes. In superconductors, the electron-phonon interaction leads to the formation of a superconducting gap below the critical temperature $T_c$. These phenomena can be well described within the Eliashberg theory which extends the ES theory to the superconducting state (Sec. IIIC2). Finally, conclusions are drawn in Sec. IV.

The system that is considered for this analysis is the graphite intercalated compound CaC$_6$. This material has the highest superconducting $T_c$ observed so far (11.5 K) amongst the group of graphitic compounds. Graphite related materials have attracted considerable interest in the last few years, mostly due to the appealing possibility of tuning their physical properties by adjusting the level of intercalation. In Ca intercalated graphite superconductivity arises from the strong electron-phonon coupling provided both by C and Ca phonon modes. This coupling is strongly anisotropic with C and Ca related phonons acting selectively on the multiple Fermi Surface (FS) sheets of the systems. These peculiarities make the system particularly interesting.

The paper is organized as follows: In Sec. I, the main concepts and physical quantities describing our results are introduced by reviewing the Eliashberg theory of superconductivity. Sec. II is devoted to a detailed description of the principal computational techniques employed in this work. In Sec. III, results for CaC$_6$ are discussed. Sec. IIIA reports on the structure of the electron-phonon interaction. Sec. IIIB focuses on the numerical solutions of the Eliashberg equations with a $\mu^*$ determined using results from Density Functional Theory for Superconductors (SCDFT) calculations. In Sec. IIIC, the polaronic features of the excitation spectrum of CaC$_6$ are elucidated, both in the normal state (Sec. IIIC1) and in the superconducting state (Sec. IIIC2). Finally, conclusions are drawn in Sec. IV.
I. METHODS

Central quantity in the Nambu-Gor’kov formalism of superconductivity is the $2 \times 2$ Green’s function:

$$\bar{G}(\mathbf{k},i\omega_n) = \frac{G(\mathbf{k},i\omega_n) - F(\mathbf{k},i\omega_n)}{-F^\dagger(\mathbf{k},i\omega_n)G(\mathbf{k},-i\omega_n)},$$

(1)

where $G(\mathbf{k},i\omega_n)$ and $F(\mathbf{k},i\omega_n)$ are, respectively, the normal and anomalous electronic Green’s functions in reciprocal space. $\omega_n$ are the Fermionic Matsubara frequencies given by $\omega_n = \pi(2n+1)k_BT$ with $T$ being the temperature and $k_B$ the Boltzmann constant. Following a well established procedure, non-interacting Kohn-Sham system with Green’s function $\bar{G}_0(\mathbf{k},i\omega_n) = [i\omega_n\sigma_0 - \xi_\mathbf{k}\sigma_3]^{-1}$, is used as a starting point. Here $\sigma_j$ ($j=0,...,3$) are the Pauli matrices and $\xi_\mathbf{k}$ are the Kohn-Sham eigenvalues relative to the Fermi energy. The interacting Green’s function can then be obtained using perturbation theory:

$$[\bar{G}(\mathbf{k},i\omega_n)]^{-1} = [\bar{G}_0(\mathbf{k},i\omega_n)]^{-1} - \Sigma(\mathbf{k},i\omega_n).$$

(2)

The following approximation for the electronic self-energy is used:

$$\Sigma(\mathbf{k},i\omega_n) = -k_BT \sum_{\mathbf{k}',\mathbf{n}',\mathbf{n}} \sigma_3 \bar{G}(\mathbf{k}',i\omega_{n'})\sigma_3 \times \left[ \sum_\nu |g_{\mathbf{k},\mathbf{k}',\nu}|^2 D_{\nu}(\mathbf{k}-\mathbf{k}',i\omega_n-i\omega_{n'}) + \sigma_1 W(\mathbf{k}-\mathbf{k}') \right]$$

(3)

where $D$ is the phonon propagator ($D = -2\omega_{\mathbf{q},\nu}/(\omega_n^2 + \omega_{\mathbf{q},\nu}^2)$), $g_{\mathbf{k},\mathbf{k}',\nu}$ are the electron-phonon matrix elements between states with wavevector $\mathbf{k}$ and $\mathbf{k}'$, and due to a phonon mode of index $\nu$ and wavevector $\mathbf{q}=\mathbf{k}-\mathbf{k}'$ and $\omega_{\mathbf{q},\nu}$ is the frequency of the mode obtained via linear response of the Kohn-Sham system. This way of calculating $\omega_{\mathbf{q},\nu}$ is known to lead to a very good agreement with the measured phononic branches, at least for standard metals and insulators. $W$ in Eq. (3) is the screened static electron-electron interaction, it accounts for those parts of the interaction which do not involve any phononic contribution. The $\sigma_1$ factor in front of $W$ accounts for the fact that exchange and correlation effects are already included in $\bar{G}_0(\mathbf{k},i\omega_n)$.

Then only off-diagonal contributions of $W$ are retained in $\Sigma$.

The treatment of the Coulomb term needs particular care. Within Eliashberg theory, an arbitrary cut-off in $\mathbf{k}$ space is needed in order to avoid serious divergency problems in the Matsubara summation. A conventional way to deal with this problem is to choose an energy cut-off of the order of the Fermi energy, and to assume that the product of $W$ with the density of states (DOS) is constant: $\mu = WN$, $N$ being the DOS per spin at the Fermi energy. It is then possible to restrict the Matsubara integration to a low energy (a fraction of eV) by a renormalization procedure $\mu \to \mu^*$ introduced by Morel and Anderson. $\mu^*$ can be calculated within the random phase approximation (RPA) and the resulting $T_c$ are usually in reasonable agreement with experiments. However, usually $\mu^*$ is adjusted to obtain the experimental $T_c$.

The self-energy in Eq. (3) is $\mathbf{k}$-dependent and leads to anisotropic Eliashberg equations which are computationally very demanding. A simplification can be introduced retaining a minimal anisotropic structure needed for the properties of interest. The FS may be divided into portions (FS sheets), with each sheet identifying a corresponding intersecting energy band. These FS sheets and energy bands can be labeled using the same index (say, J). We shall refer to such a division as to a multi-band decomposition (details of our procedure are given in Sec. IIIA).

The electron-phonon coupling can be averaged over a prescribed multi-band divisions (see below, Eqs. (10) and (11)). Corresponding, multi-band resolved self-energy, $\Sigma_J$, expanded in the basis of Pauli matrices has a form:

$$\Sigma_J(n) = i\omega_n [1 - Z_J(n)]\sigma_0 + \Delta_J(n)Z_J(n)\sigma_1,$$

(4)

(terms which only result in a rigid shift of the Fermi level are neglected). The multi-band resolved Green’s function reads:

$$\bar{G}_J(\mathbf{k},i\omega_n) = \frac{\left( i\omega_n Z_J(n) + \xi_{\mathbf{k}} \Delta_J(n) Z_J(n) \right)}{ \left( [Z_J(n)i\omega_n]^2 + \xi_{\mathbf{k}}^2 + [\Delta_J(n)Z_J(n)]^2 \right)},$$

(5)

where $\xi_{\mathbf{k}}$ are the Kohn-Sham eigenvalues in the J-th band.

Using Eqs. (1) and (4) in the Dyson equation, we arrive at the following set of coupled self-consistent equations:\cite{5,23,20}.

$$Z_J(n) = 1 + \frac{\pi k_BT}{i\omega_n} \sum_{m,J'} \lambda_{J,J'}(n,m) \frac{i\omega_m Z_J(m)}{R_{J'}(m)},$$

(6)

$$\Delta_J^{ph}(n) = \pi k_BT \sum_{m,J'} \mu_{J,J'}(n,m) \frac{\Delta_J(m)Z_J(m)}{R_{J'}(m)},$$

(7)

$$\Delta_J^G(n) = -\pi k_BT \sum_{m,J'} \mu_{J,J'}(n,m) \frac{\Delta_J(m)Z_J(m)}{R_{J'}(m)},$$

(8)

$$R_J(n) = \sqrt{\omega_n^2 + \Delta_J^G(n)^2} Z_J^2(n),$$

(9)

$$\lambda_{J,J'}(n,m) = \int d\omega \frac{\omega^2}{(\omega_n - \omega)^2 + \omega^2}.$$
diagonal contributions stemming from $W$ are already accounted at the level of the normal state Kohn-Sham system, $Z_J(n)$ has a purely phononic character.

The off-diagonal Coulombic contributions are accounted by the FS-dependent $\mu_{j,k}^*$. In this work, we choose $\mu_{j,k}^*$ in such a way to reproduce the gap structure obtained within SC-DFT\cite{8,9} (we shall come back to this point in Sec. III B). Since $\Delta_J(n)$ goes to zero for frequencies much larger than the phononic scale, the cut off $\omega_c$ in the Matsubara frequency introduced for Coulombic terms can be uniformly applied to all the terms of the Eliashberg equations.

\[
\alpha^2 F_{J,J'}(\omega) = \frac{1}{N_J} \sum_{k \in J} \sum_{k' \in J'} \delta(\xi_k) \delta(\xi_{k'}) \delta(\omega - \omega_{q,v}) |g_{k,k'}|^2, \tag{11}
\]

where $N_J$ is the density of states per spin at the $J$-th FS portion.

Once the gap function $\Delta_J(n)$ and the mass renormalization function $Z_J(n)$ have been obtained on the imaginary axis solving the Eliashberg equations (Eqs. (6)–(10)), they can be efficiently continued to the real axis via Padé approximant technique\cite{11–14}, allowing the computation of the real-axis retarded Green’s function. In particular, we will deal with $G := G^{11}$ which is given by:

\[
G_J(k,\omega) = \frac{\omega Z_J(\omega) + \xi_{Jk}}{[\omega Z_J(\omega)]^2 - \xi_{Jk}^2 - [\Delta_J(\omega) Z_J(\omega)]^2}, \tag{12}
\]

with the corresponding spectral function defined as:

\[
A_J(k,\omega) = -\frac{1}{\pi} \text{Im} G_J(k,\omega). \tag{13}
\]

The energy and life time of a quasi-particle are given by the real part and (the absolute value of the) imaginary part of the pole positions, respectively. The spectral function may have broader structures and, thus, the concept of quasi-particle may not apply rigorously. In order to extract the main features, we look for the zero, $\omega_p$, of the denominator of $G$, i.e. we look for solutions of the equation:

\[
\omega_p = \sqrt{\xi_{Jk}^2 + [\Delta_J(\omega_p) Z_J(\omega_p)]^2} \tag{14}
\]

in the complex plane.

II. COMPUTATIONAL DETAILS

Electronic eigenvalues, phononic frequencies, and electron-phonon matrix elements are calculated using the ESPRESSO pseudopotential based package\cite{15–17}. All calculations are done using the GGA (Generalized-Gradient Approximation) with the Perdew-Wang\cite{18} parameterization for the exchange-correlation functional. UltraSoft pseudopotentials\cite{19} are employed. A 30 Ry cut-off is fixed for the planewave expansion of the wavefunctions and 300 Ry for the electronic charge. The Brillouin zone is sampled with a $6 \times 6 \times 6$ k-point grid, and electron-phonon matrix elements are obtained on a $10 \times 10 \times 10$ grid. More details can be found in Ref. 22.

The double Brillouin zone integration appearing in the definition of the band-resolved Eliashberg functions in Eq. (11) is evaluated with a Metropolis integration scheme. Random k-points are generated on the Brillouin zone, then each k-point is accepted or rejected with a probability depending on $\xi_{k}$, and its weight is inversely proportional to the acceptance probability. We use a set of about $2 \cdot 10^4$ accepted k-points per band. Then electron-phonon matrix elements on this random mesh are obtained via interpolation from those calculated on the regular grid.

Eliashberg equations are solved using a 2500 meV cut-off of the Matsubara frequencies, with the cut-off $\omega_c$ for the Coulombic interaction equal to 500 meV. Both parameters are much larger than the maximum phonon frequency of CaC$_6$, which is about 200 meV. The number of Matsubara frequencies at each temperature is fixed by the energy cut-offs, and the M Matsubara frequencies on the positive imaginary axis are used to construct $(M,M)$ Padé approximants which are used for the analytic continuation\cite{23,24} to the real axis.

III. RESULTS AND DISCUSSION

A. Properties of the electron-phonon coupling

We calculate the Eliashberg function defined by Eq. (11) in three different ways:

- Averaging the electron-phonon coupling over the full surface: referred to as 1-band FS or isotropic approximation.
- Splitting the FS into three parts: this is shown with three different colors in the FS (see Table I). The division of the Fermi surface leads to a division in the electronic bands shown in the band structure plot of Fig. 3, an electronic band and a portion of the FS have same color if they intersect. The first portion FS 1 is the external FS sheet (shown in green), which comes from $\pi$ states. FS 2 (shown in blue) is the spherical Ca Fermi surface. FS 3 (shown in red) is the $\pi$-prism, a two-dimensional FS having the shape of a hexagonal prism which crosses the spherical Ca Fermi surface (the corresponding electronic band is the band 3). This division is referred to as the 3-band FS approximation.
- Splitting the FS into six parts: each of the three portions in the 3-band FS approximation is further
FIG. 1: (color online) 3-band FS resolved \( \alpha^2 F_{JJ'}(\omega) \) of CaC\(_6\). The three panels refer to the incoming FS, from which the electron is scattered, while the three lines in each panel refer to the outgoing FS.

split into two parts. The above \( \pi \) (external) FS has been divided into a less coupled\(^{22}\) outer part with \( |k_{xy}| > 0.4 \) a.u., and the rest; these two portions are referred to as 1a and 1b portion, respectively. The Ca spherical Fermi surface is cut into 2a portion (with \( |k_z| < 0.18 \) a.u.) and the 2b portion (the rest). 3a and 3b portions for the \( \pi \)-prism are defined in a similar manner. The same boundaries are used to further split the corresponding energy bands. This overall division is called the 6-band FS approximation.

In Table I is presented the DOS at the Fermi level, the intra- and the inter-band electron-phonon couplings:

\[
\lambda_{JJ'} = 2 \int \frac{\alpha^2 F_{JJ'}(\omega)}{\omega} d\omega .
\]  

In the 3-band FS approximation the interaction is dominated by the off-diagonal coupling terms, especially by the inter-band scattering from states on the spherical Ca Fermi surface to states on the \( \pi \)-bands. The main reason for this is a strong electron-phonon coupling in the former (from 2 to 1) and large DOS in the latter (from 2 to 3). The full 3-band \( \alpha^2 F_{JJ'}(\omega) \) matrix (see Fig. 1) shows the distribution of the coupling among the various phonon modes—band 2 couples strongly with Ca modes (giving a low frequency peak around 10 meV) while, band 1 couples mainly with the high-frequency stretching C modes (at 170 meV). Band 3 shows the most homogeneous coupling (its intra-band spectral function looks similar in shape to the total Eliashberg function).

The further decomposition into the 6-band FS approximation doesn’t introduce qualitative differences with respect to the 3-band decomposition but, as we shall show, it results in a better quantitative description of the anisotropy of the superconducting properties.

|        | 1     | 2     | 3     |
|--------|-------|-------|-------|
| 1a     | 0.163 | 0.126 | 0.099 |
| 1b     | 0.179 | 0.140 | 0.105 |
| 2a     | 0.331 | 0.245 | 0.151 |
| 2b     | 0.271 | 0.202 | 0.206 |
| 3a     | 0.252 | 0.194 | 0.145 |
| 3b     | 0.206 | 0.157 | 0.128 |
| DOS    | 0.412 | 0.104 | 0.249 |

TABLE I: Electron-phonon coupling \( \lambda_{JJ'} \) and DOS for the 3-band FS (top) and 6-band FS (bottom) divisions. DOS is given in states/eV/spin. The first index runs over the columns. Isotropic DOS and \( \lambda \) are 0.787 and 0.870, respectively. The picture on the top represents the FS of CaC\(_6\): the external portion in green; the internal sphere in blue; and the hexagon that cuts the sphere in red. The labels “a” and “b” correspond to the additional splitting defining the 6-band division.

B. Solution of Eliashberg equations

The Eliashberg equations are solved in three different ways corresponding to three ways in which the Eliashberg function defined in section III. The solution to the Eliashberg equations lead to a strong anisotropy in the gap (see Fig. 2); the smallest gap corresponds to the 2a structure which forms the central part of the Ca spherical Fermi surface. We note that at the phononic level, the anisotropic structure obtained here agrees very well with the one obtained within SCDFT in Ref. 22 (see panels (e) and (f) in Fig. 2). If the \( T_c \) is determined from this gap function, without including the Coulomb interaction, it is not strongly affected by the multi-band character (i.e. the anisotropy of the gap function); the isotropic \( T_c \) is about 33.5 K and only slightly higher in the 6-band case with a value of 34 K.

In order to include the Coulomb interactions the matrix \( \mu^*_{JJ'} \) is needed. Typically \( \mu^*_{JJ'} \) is determined by fitting to the experimental data. However, for CaC\(_6\) the SCDFT gap well reproduces the experimental measurements\(^{23–37}\). Therefore, in this work, we determine \( \mu^*_{JJ'} \), fitting to the gap structure obtained from SCDFT.

Interestingly, the simple semi-isotropic approximation: \( \mu^*_{JJ'} = \mu^* N_J / N \), turns out to be sufficient to reproduce the SCDFT gap. In the 6-band FS approximation the experimental \( T_c = 11.5 \) K is reproduced for \( \mu^* \simeq 0.21 \) [see
interacting (c) in Fig. 2. With this choice of μ'_J,J' the inclusion of Coulombic effects reduces the \( T_c \) without significantly affecting the anisotropic structure of the superconducting gap. The only difference is that by including the Coulombic interaction the gap corresponding to the 2b portion of the FS becomes slightly larger than the 3a portion (see Fig. 2(d)). This choice of a semi-isotropic Coulombic pairing which is often done in Eliashberg theory can be validated by the present analysis. However, this cannot be applied as a general rule; it has been shown, in cases like in MgB\(_2\), that a more detailed Coulombic structure is necessary to get the correct gap anisotropy.

Both \( \Delta(n) \) and \( Z(n) \) are purely real-valued on the Matsubara frequencies. For the isotropic case the frequency dependence of \( \Delta(n) \) and \( Z(n) \) is shown in Fig. 3(a). It is clear that \( Z(n) \) has a value of \( 1 + \lambda \) for small \(|n|\) and then monotonically decreases to 1 at energies much larger than the available phonons. This behavior is almost independent of the values of \( \mu^* \) and temperature. The \( \Delta(n) \) function also monotonically decreases as a function of increasing energy. The low-energy value is the fundamental superconducting gap, while in the high-energy limit approaches \( \Delta^C(n) \). For an isotropic and static Coulomb interaction, \( \Delta^C(n) \) is both independent of \( k \) and the Matsubara frequencies. More physical features emerge from the analytic continuation to the real axis. In particular, we see a three-peak structure in both the real and imaginary parts of \( Z(n) \) that correlates with the peaks in the \( \alpha^2 F_{J,J'}(\omega) \).

C. Analysis of self-energy effects

1. Normal state: isotropic approximation

We discuss in this section the simplest case in which the Eliashberg equations are solved above \( T_c \). Since \( T_c \) is quite low with respect to the phonon energies, solution above \( T_c \) is almost equivalent to imposing the solution at \( \Delta = 0 \) when \( T = 0 \). In this section, we use only the isotropic solutions of the Eliashberg equations and a parabolic band dispersion.

The solution of the Eliashberg equations give \( Z(\omega) \) which is shown in Fig. 3(c) (black line). Using \( Z(\omega) \) as input, Eq. (11) is solved in order to obtain the quasi-particle dispersion curves reported in Fig. 4(a). This figure shows how the unperturbed electronic band, by getting dressed with the phononic self energy, develop branches in correspondence with the three main phononic peaks in the Eliashberg function. These electronic quasi-particles dressed by the electron-phonon interaction, so called polarons, are nearly dispersionless. Only one dispersive branch, that goes to zero from about 50 meV, is observed. This structure also has a very short lifetime (\( \sim 100 \) meV). All the polaronic modes have instead a longer lifetime (between 1 and 10 meV) and thus appear as sharp quasi-particles. However, the po-
laronic branches, carry very little of the total spectral weight. Most of the spectral weight is still localized near the bare electron dispersion line. This can also be seen in Fig. 1(b), where the spectral function is shown in the same energy/momentum window as the quasi-particle plot. In this case, we see how the main electron band acquires a finite lifetime and instead of branchings only kinks appear. These kinks correspond to the three main peaks in the $\alpha^2 F(\omega)$.

To move from a qualitative description to a more quantitative one, the spectral function $A(\omega)$ is examined (see Fig. 1(c)). At $k = k_F$ more than 50% of spectral weight is accounted for by a single peak of infinite lifetime at the Fermi energy. This peak (single green line in Fig. 1(c)) moves to higher energies with increasing k-vector (slowly growing in width) up to an energy of about 10 meV, where it merges with the polaronic branch generated by the low-frequency Ca modes (blue long-dashed line). Above 10 meV the peak is broader (blue thick line) because the electrons can relax through the generation of Ca phonons. This broad peak then behaves in a similar way as the narrow peak below 10 meV; i.e., it increases in energy with $k$ up until it merges with another polaronic band which originates from the low-frequency C modes (red dot-dashed line) and has an energy $\sim$ 50 meV. It becomes very broad (yellow short-dashed line) and is difficult to follow as it merges with the high-frequency C mode. This behavior is very similar to the case of the Einstein phonons discussed by Engelsberg and Schrieffer in Ref. 1. In our case, this is due to the three-peak structure of the $\alpha^2 F(\omega)$ i.e. due to the combined effect of the two-dimensionality of graphite along with the presence of weakly bound Ca ions. Therefore, at the isotropic level the self-energy effects in CaC$_6$ (type described by Eq. 6) are particularly simple.

2. Normal and superconducting states: anisotropic features

The degree of complexity of our analysis is increased by making use of the real KS band dispersions of CaC$_6$. Multiple FSs that couple with different phonon branches are accounted for by adopting the 6-band decomposition. As shown in Fig. 1(c), (d), (e), and (f), the Ca band couples mostly with low-frequency modes, therefore it shows polaronic structures only up to 50 meV. One single kink can be observed in the spectral function at 50 meV. The kink at 10 meV is not visible simply because below this frequency the spectral function itself is just a sharp peak.

The band that has most structures is the one that produces the $\pi$-prism FS (Fig. 1(g), (h), and (i)), due to the coupling of all three sets of modes. The external FS, which couples mostly with high-frequency C modes, shows only a weak kink around 160 meV. The polaronic branchings (Fig. 1(b), (c), (d), (h), and (i)) have similar structures as observed in the isotropic limit. Anisotropic features are less marked than in the spectral function, because Eq. 1 used to determine these features does not retain information about the spectral weight in the branches.

The spectral function in the superconducting phase is gapped and the multi-gap features can be clearly seen in the lower panels of Fig. 5(b), (c), (f), and (g). The gap ranges from 1.5 meV around the point $b$ in the band structure (Fig. 5(b)) to about 2.2 meV around point $c$ (Fig. 5(c)). The spectral function shows a (textbook-like) hyperbolic dispersion—this is the signature of Bogoljubov excitations, as compared to the normal electronic excitations which have a linear band dispersion (see Fig. 4(c) and (c')). The distance between the vertices of the hyperbola is equal to $2\Delta(0)$. As the temperature rises to approach $T_c$, $\Delta(0) \rightarrow 0$ and the hyperbola tends to its asymptotes. At the same time the spectral weight of the two reflected components (right part of the upper branch and left part of the lower branch in Fig. 5(c')) also goes to zero and the excitation spectrum becomes normal (Fig. 5(c')).

One of the two arms of this hyperbolic dispersion corresponds to the normal electronic dispersion line, and it behaves in a similar way as in the non-superconducting state. The other arm that is a unique feature of the Bogoljubov excitations loses spectral weight as the distance from the FS increases. However as it reaches the energy of the Ca in-plane modes (from 10 to 15 meV) it deviates from the hyperbolic arm and follows a polaronic (dispersionless) behavior. One can appreciate the formation of this dispersionless Bogoljubov polaron in the upper-right and lower-left corners of panel (b') in Fig. 5.

IV. CONCLUSIONS

Superconductivity in the graphite intercalated compound CaC$_6$ is studied using Eliashberg theory and superconducting density functional theory. Within a multi-band description and assuming a structureless Coulomb interaction, we performed a detailed analysis of the influence of strongly anisotropic electron-phonon coupling on the $k$-dependence of the superconducting gap. Anisotropies computed with Eliashberg theory and superconducting density functional theory were found to be in very good agreement with each other and with experiments.

In this context, from the solution of the Eliashberg equations, we have shown how anisotropic polaronic bands emerge over different Fermi surface sheets. The interplay between superconducting (Bogoljubov) excitations and polarons has also been studied. We reported, for the first time, how Engelsberg-Schrieffer polarons evolve from the normal state to the superconducting state in CaC$_6$. 
FIG. 4: (color online) Polaronic bands and spectral function for the normal state in the isotropic approximation. On panel (a), the polaronic quasi-particle dispersion curves are shown. This is obtained from the real and imaginary part of the solution of Eq. (14). The inverse lifetime of the state is given by $|\text{Im}(z_p)|$ and it is reported for some points as “error-bar”. Panel (b) shows the spectral function $A(k, \omega)$. The abscissa represent the $|k|$ axis, and the point in which $A(k, \omega)$ crosses is $k_F$. In ordinate, the frequency axis is reported. The color-scale goes from zero to about $15 \text{ eV}^{-1}$ (note that, we cut it off to enhance the structures of $A(k, \omega)$). Panel (c) shows $A(k, \omega)$ for different values of the momentum. A few values are highlighted and correspond to $k$-values indicated in panel (b). Panel (d) shows $\alpha^2 F(\omega)$ computed in the the isotropic 1-band approximation.

Padé approximants were used to continue solutions of the Eliashberg equations to the real axis. Very good agreement is observed in the full energy spectrum for the $Z(\omega)$ function. Although the analytically continued gap function $\Delta(\omega)$ shows some deviations from the exact solutions, this happens in the $\sim 0.1$ eV energy region. As a result, this doesn’t introduce sizeable errors in our estimation of the spectral function.
FIG. 5: (color online) Polaronic bands and spectral function for the anisotropic and superconducting states of CaC\(_6\) determined within the 6-band approximation. Central panel shows the band structure of CaC\(_6\): the continuous green line is the C\(\pi\) band corresponding to FS 1; the blue dot-dashed line is the Ca inter-layer band corresponding to FS 2; and the red dashed line is the second C\(\pi\) band corresponding to FS 3 (see Table I for plots of the several FS portions). Further subdivisions are not reported explicitly. Panels from (a) to (i) show the spectral function near the Fermi energy in a wide energy window of 300 meV. The letters correspond to the labeling of the crossing points in the central panel. The color-scale goes from zero (black) to 15 eV\(^{-1}\) (white). Higher peaks in the spectral function have been cut off. Panels with a primed index show the quasi-particle spectrum (see text for details). These also show the polaronic branches together with the main electronic band. Colors are proportional to the line-width of the quasi-particle state: black corresponds to zero and yellow/white correspond to about 0.1 eV. Panels (b\(\ast\)), (c\(\ast\)), (f\(\ast\)), and (h\(\ast\)) – focusing on the superconducting gap (a logarithmic color-scale is used) – show a zoom of the spectral function near the Fermi energy in a narrow energy window of 20 meV. Panel (c\(\#\)) is the same as (c\(\ast\)) but evaluated in the non-superconducting state.
