PURPOSE. Limbal epithelial stem cells (LSCs), located in the basal layer of the corneal epithelium in the corneal limbus, are vital for maintaining the corneal epithelium. LSCs have a high capacity of self-renewal with increased potential for error-free proliferation and poor differentiation. To date, limited research has focused on unveiling the composition of the limbal stem cell niche, and, more important, on the role the specific stem cell niche may have in LSC differentiation and function. Our work investigates the composition of the extracellular matrix in the LSC niche and how it regulates LSC differentiation and function.

METHODS. Hyaluronan (HA) is naturally synthesized by hyaluronan synthases (HASs), and vertebrates have the following three types: HAS1, HAS2, and HAS3. Wild-type and HAS and TSG-6 knockout mice—HAS1−/−;HAS3−/−, HAS2Δ/C0CorEpi, TSG-6−/−—were used to determine the importance of the HA niche in LSC differentiation and specification.

RESULTS. Our data demonstrate that the LSC niche is composed of a HA rich extracellular matrix. HAS1−/−;HAS3−/−, HAS2Δ/C0CorEpi, and TSG-6−/− mice have delayed wound healing and increased inflammation after injury. Interestingly, upon insult the HAS knock-out mice up-regulate HA throughout the cornea through a compensatory mechanism, and in turn this alters LSC and epithelial cell specification.

CONCLUSIONS. The LSC niche is composed of a specialized HA matrix that differs from that present in the rest of the corneal epithelium, and the disruption of this specific HA matrix within the LSC niche leads to compromised corneal epithelial regeneration. Finally, our findings suggest that HA has a major role in maintaining the LSC phenotype.

Keywords: limbal stem cells, hyaluronan, corneal epithelial cells, stem cell niche

The ocular surface is composed of the cornea surrounded by the conjunctiva, and the transition between these is the limbus. The cornea, conjunctiva, and limbus form a continuous epithelial layer. Previous studies provide evidence that the cornea contains a stem cell niche at the basal epithelial layer of the limbus.1,2 Limbal stem cells (LSCs), located in the basal layer of the corneal epithelium in the corneal limbus, have a vital role in maintaining the cornea. LSCs have a high capacity of self-renewal with increased potential for error-free proliferation and poor differentiation.3–6 LSCs also have a long cell cycle, small cell size, high nuclear to cytoplasm ratio, and asymmetric division.7 After cell division, one daughter cell maintains the LSC stemness while the other daughter cell becomes a transient amplifying cell (TAC), with increased proliferative potential.8–11 TACs migrate out of the stem cell niche and ultimately differentiate into corneal epithelial cells.9 LSCs are required for reconstituting the corneal epithelium after injury and also have an important role in preventing conjunctival epithelial cells from migrating onto the surface of the cornea. Moreover, limbal stem cell transplantation is capable of restoring the eyesight to a severely damaged ocular surface resulting in rapid corneal re-epithelialization without persistent erosions. Currently, limbal stem cell transplantation is a common surgical procedure that is carried out around the world.12–16 In humans, the corneoscleral limbus has a series of radially oriented ridges, namely the palisades of Vogt, where the LSCs are located.17–19 LSCs express various stem cell markers, such as cytokeratin 15 (K15), ΔNp63α, and ABCG2, and lack differentiated corneal epithelial markers such as cytokeratin 3 and cytokeratin 12 (K12).19–25

Limb stem cell deficiency (LSCD) is a condition caused by damage or loss of LSCs. LSCD is a serious medical condition that leads to corneal opacification, inflammation, vascularization, and severe pain and may lead to the complete loss of vision.9,24,25 A hallmark of LSCD is the migration of conjunctival cells onto the cornea leading to conjunctivalization, which results in severe vision loss and requires corneal transplantation.3,26 Substantial research has been dedicated to developing new therapeutic approaches for treating LSCD. An emerging surgical approach is the transplantation of LSCs expanded ex vivo from either the residual LSCs of a patient or from a human leukocyte antigen-matched donor.9,27–29 However, many LSCD patients present nonresolving inflammation, which limits the success of corneal and LSC transplantation.30–32 Studies have
shown the great therapeutic potential of amniotic membrane transplantation for treating LSCD. Recently, the Tseng group showed that a hyaluronan (HA) complex was responsible for the efficacy of amniotic membrane treatment. This group also went on to show that this HA complex in the amniotic cord injury and forms a principal constituent of the glial scar. We have recently shown that HA matrices present inflammatory effects and is primarily correlated with pathogen-esis. We have also recently shown that the LSC niche is composed of a HA rich matrix. Using knock-out mice for the different HAS enzymes, our results indicate that the HA matrix is necessary for maintaining the LSC phenotype. Characterization of the role of the HA matrix in the corneal LSC niche opens possible new therapeutic avenues for treating LSCD by re-establishing the LSC niche to provide the environment necessary to support LSCs.

**Materials and Methods**

**Animal Maintenance**

**Mouse Strains and Genotyping.** Transgenic mouse lines K14-rTA (stock number 008099) and teto-cre (stock number 006224) from The Jackson Laboratory were used (Bar Harbor, ME, USA). Floxed HAS2 mice, namely HAS2<sup>flox/flox</sup> Null TSG-6<sup>−/−</sup>;HAS2<sup>−/−</sup>/C0 mice, were used. Compound K14-rTA, teto-cre, and HAS2<sup>−/−</sup>/C0 transgenic mice were generated by mating. The mice were bred and housed in a temperature-controlled facility with an automatic 12-hour light–dark cycle at the Animal Facility of the University of Houston. Experimental procedures for handling the mice were approved by the Institutional Animal Care and Use Committee, University of Houston. All animal procedures adhered to the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research. The identification of each transgene allele was determined by PCR genotyping with tail DNA. Administration of doxycycline chow was used to induce K14-driven persistent and irreversible excision of HAS2 in the corneal epithelium (CorEpi) of tetratransgenic mice (K14-rTA;TC; HAS2<sup>flox/flox</sup>); generating HAS2<sup>−/−</sup>/CorEpi<sup>−/−</sup>. Transgenic mice at postnatal day 7 (P7) or P21 were fed with doxycycline chow (1 g of doxycycline/kg of chow; Custom Animal Diets LLC, Bangor, PA, USA) ad libitum. Control animals (1 g of doxycycline/kg of chow; Custom Animal Diets LLC, Bangor, PA, USA) were fed ad libitum. Control animals (1 g of doxycycline/kg of chow; Custom Animal Diets LLC, Bangor, PA, USA) were fed ad libitum.
Debridement Wound for RNA Extraction. Corneal epithelial debridement wounds (1.5 mm in diameter) were done on wild-type mice. The mice were anesthetized by intraperitoneal injection of ketamine hydrochloride (80 mg/kg) and xylazine (10 mg/kg). The corneal wound area was demarcated with a 1.5 mm-diameter biopsy punch, and the entire debridement wound was done with an AlgerBrush II (Alger Company, Inc., Lago Vista, TX, USA). Thereafter, the debrided cells were removed by washing with PBS and a sponge swab. The eyeballs were collected 2, 4, and 8 hours after debridement wounding and placed in Invitrogen RNAlater Stabilization Solution (Thermo Fisher Scientific, Wilmington, DE, USA). To analyze HAS expression in uninjured corneas, the mice (0 hours) were euthanized by CO₂ inhalation. Epithelial cells in the central cornea were removed as mentioned previously, and the corneas were immediately placed in Invitrogen RNAlater Stabilization Solution. Five eyeballs were used for each experimental point.

RNA Extraction and Real-Time PCR Analysis. The eyeballs were dissected and the corneas removed for RNA extraction. mRNA was extracted using the PureLink RNA Mini Kit (Ambion, Life Technologies, Carlsbad, CA, USA), according to the manufacturer’s instructions. cDNA was synthesized using SuperScript III First-Strand (Invitrogen), according to the manufacturer’s instructions. The primer combination used for qPCR analysis of HAS1 was 5’-CTATGGTCAACAACTGCTG-3’ and 5’TCTGGAATGTTTGCACAGG-3’, of HAS2 was 5’-CGGGTGTCCTCAAATCTCTG-3’ and 5’-ACAATGCTCATTGTTCAGCTCTG-3’, of HAS3 was 5’-GATGGCATAAATCCACAGG-3’ and 5’-GCCAATAACATCTGACAC-3’, and of TSG-6 was forward: 5’-ACGATGTCCACGGCTTTGTAGG-3’ and reverse: 5’-GACCCATCACAATCTTCAAGG-3’. Real-time PCR was done on SyberGreen and analyzed using a Biorad CFX96 C1000 Thermal Cycler (Biorad, Hercules, CA, USA). For data analysis, the 2-ΔΔCt method was used, and data were normalized to the reference genes 40S ribosomal protein S29 (RPS29) and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) using the 7500 Real-Time PCR System’s software and yielded comparable results. The data normalized to RPS29 are presented.

Histological Analysis. Eyeballs were fixed for 30 minutes in 2% buffered paraformaldehyde, washed five times with PBS, sequentially dehydrated, immersed in paraffin overnight, and subsequently mounted. The sections were sectioned at 5 μm and the sections collected on poly-L-lysine-treated slides. Upon use, the paraffin sections were washed with xylene to remove excess paraffin and then rehydrated. Subsequently, the sections were stained with hematoxylin and eosin. A Periodic-Schiff kit (395B-1KT, Sigma-Aldrich Corp., St. Louis, MO, USA) was used for detecting goblet cells in the corneas of HAS2 CorEpi mice according to the manufacturer’s instructions. In short, contained alkali burns were produced by placing circular 3MM chromatography paper (1-mm diameter; Whatman, Little Chalfont, Buckinghamshire, United Kingdom) soaked in 0.1 M sodium hydroxide onto the central cornea for 1 minute and 15 seconds. Subsequently, the eyes were continuously washed with sterile PBS for 1 minute. This contained alkali burn protocol avoids damaging the limbal stem cells, which allows comparisons of the effects of HA depletion on suppression of inflammation and regeneration of a transparent cornea without depleting LSCs through the alkali burn procedure itself. Finally, terramycin ointment was topically administered to the eyes, and the animals were placed on a warming pad. A total of 20 mice were used for each experimental point, and 12 were processed for histological analysis and eight for whole-mount staining.

Immunohistochemistry. Paraffin sections were heated at 65°C for 30 minutes and subsequently washed with xylene to remove excess paraffin and then rehydrated. Unspecific protein binding sites were blocked with 5% fetal bovine serum (FBS). Sections were then incubated with a primary antibody anti-Krt14 (PRB-155P; Covance, Princeton, NJ, USA), rabbit anti-Krt14 (PA5-16722; ThermoFisher Scientific), rabbit anti-Krt12 (ab185627; Abcam, Cambridge, MA, USA), mouse anti-Krt15 (LHK15; ThermoFisher Scientific), goat anti-ionized calcium-binding adapter molecule 1 (Iba1) (ab5076; Abcam), and rat anti-F4/80 (ab6640; Abcam). Sections were washed and incubated with appropriate secondary donkey antibodies conjugated with Alexa Fluor 488 or Alexa Fluor 555 for 1 hour at 18°C. For HA staining, corneas were incubated with biotinylated HA binding protein (HABP-385911; Millipore, Billerica, MA, USA) followed by NeutraAvidin Alexa 555 (Life Technologies, Carlsbad, CA, USA). For whole-mount staining, corneas were excised from enucleated eyeballs, treated for 15 minutes in 0.1% sodium borohydride, and the unspecific protein binding sites were blocked with 5% FBS for 24 hours with shaking. The corneas were then incubated with a primary antibody, rabbit anti-Krt12, rabbit anti-Krt14, mouse anti-Krt15, rat anti-F4/80 (ab6640; Abcam) or mouse anti-α-smooth muscle actin (SMA; clone 1A4; Sigma-Aldrich), for 24 hours followed by the secondary donkey antibodies conjugated with Alexa Fluor 488.
seven eyeballs were used for each experimental point. Using a Zeiss Discovery.V12 Stereo Microscope (Zeiss). At least excess removed with PBS washes. The eyeballs were imaged was placed over the mouse eyeballs for 1 minute, and the 0.35%/0.4% (Apollo Ophthalmics, Newport Beach, CA, USA) Disodium & Benoxinate Hydrochloride Ophthalmic Solution continuous collected from the corneal epithelium to the endothelium as a in vivo confocal microscopy prior to euthanasia.

**RESULTS**

**Detection of HA in the LSC Niche**

The composition of the LSC niche was investigated by immunostaining the corneas of C57BL/6j mice for numerous extracellular matrix components. Our objective was to find molecules differentially expressed in the limbal region when compared with the rest of the corneal epithelium. Of all the molecules investigated, we found that HA was primarily expressed in the LSC niche (Figs. 1B, 1C). HA staining was present in all the epithelial layers in the corneal limbal region (Fig. 1B). The HA forms a net-like network within the corneal limbus and cable-like structures (arrows) that extend from the limbus into the peripheral cornea (Fig. 1C). The specificity of HA expression to the limbal stem cell niche led us to investigate the role of HA in maintaining the limbal stem cell niche.

**Analysis of the HAS1, HAS2, and HAS3 Expression Profiles**

Three HA synthases, HAS1, HAS2, and HAS3, can synthesize HA. To date no studies have assessed which of the HAS enzymes are expressed in the corneal tissue. Therefore, RNA was extracted from uninjured corneas (referred to as 0 hours) and from corneas at 2, 4, and 8 hours after a debridement wound and analyzed by qPCR to quantify the expression of HAS1, HAS2, and HAS3. To ensure that RNA was extracted solely from the corneal limbus in the uninjured mice, the mice were euthanized, and an Algerbrush was then used to remove the central epithelial cells. Therefore RNA was extracted from limbal epithelial cells and not from corneal epithelial cells. Interestingly, our results show that all three HAS mRNAs are expressed in the cornea (Fig. 2). The uninjured cornea presents all three mRNAs, with HAS2 mRNA expression much higher, indicating that in the healthy cornea the LSC niche may be maintained by all three HAS enzymes but with HAS2 likely to be predominant. Two hours after a debridement wound to the corneal epithelium, HAS1 mRNA

Fluor 488 or Alexa Fluor 555. For HA staining, the corneas were incubated with HA binding protein for 8 hours at 4°C followed by NeutrAvidin Alexa 555. The sections and tissues were then washed and nuclei stained with 4',6-diamidino-2-phenylindole (DAPI; Sigma-Aldrich). The sections were mounted in Prolong Gold (Molecular Probes, Eugene, OR, USA) and corneas mounted in Fluoromount-G (Electron Microscopy Sciences, Hatfield, PA, USA). Images were captured using a ZEISS LSM 800 Confocal microscope with Airyscan and analyzed using the Zen software (Zeiss). Macrophages and SMA positive (SMA(α)) cells were counted by two separate investigators in a blinded manner. Secondary isotype controls were done with a rabbit IgG isotype control (ab91353; Abcam) and mouse IgG1 isotype control (ab37415; Abcam) in place of the primary antibody and did not yield any significant staining (results not shown).

**Transmission Electron Microscopy** Cornea samples were fixed in 0.1 M cacodylate buffer (pH 7.4) containing 2% glutaraldehyde overnight. Samples were rinsed in 1% osmium tetroxide for 1 hour at 4°C, washed in 0.1 M cacodylate buffer (pH 7.4) three times for 10 minutes each, dehydrated in a graded ethanol series, and embedded in Epon 812 epoxy resin (Polysciences, Inc., Warrington, PA, USA). Ultrathin 50-nm sections were obtained and stained with uranyl acetate and lead citrate, and the images captured with a Hitachi 7500 transmission electron microscope (Hitachi, Tokyo, Japan) equipped with an Advanced Microscopy Techniques (AMT) digital camera. At least three eyeballs were used for each experimental point.

**In Vivo Confocal Microscopy** Analyses of corneal structures and stromal haze were done with a Heidelberg Retinal Tomograph-HRTIII Rostock Cornea Module (Heidelberg Engineering, Inc., Heidelberg, Germany) according to the manufacturer’s instructions. Briefly, GenTeal Gel (Novartis Pharmaceuticals Corp., East Hanover, NJ, USA) was applied to both the eyeball and the tip of the Heidelberg Retinal Tomograph-HRTIII Rostock Cornea Module objective as immersion fluid. Subsequently, a series of 40 images were collected from the corneal epithelium to the endothelium as a continuous z-axis scan through the entire cornea at 2 μm to 5 μm increments. All mice used in this study were analyzed by in vivo confocal microscopy prior to euthanasia.

**Fluorescein Staining** A drop of Fluor-Safe Fluorescein Disodium & Benoxinate Hydrochloride Ophthalmic Solution 0.3%/0.4% (Apollo Ophthalmics, Newport Beach, CA, USA) was placed over the mouse eyeballs for 1 minute, and the excess removed with PBS washes. The eyeballs were imaged using a Zeiss Discovery.V12 Stereo Microscope (Zeiss). At least seven eyeballs were used for each experimental point.

**Statistical Analysis**

All values are presented as means ± standard deviation of the mean. The difference between two groups was compared by Student’s t-test. *P* ≤ 0.05 was considered to be statistically significant. Statistical analysis was done using the GraphPad Prism version 7 software package (GraphPad Software, San Diego, CA, USA).
expression increased by 19-fold while HAS2 mRNA decreased 0.5-fold (Figs. 2A, 2B). These results provided evidence that immediately after injury HAS1 may be primarily responsible for the synthesis of HA. At 4 hours after injury, HAS1 mRNA expression dropped and remained at the same 8 hours; however, the expression levels at 4 and 8 hours were still ~4-fold higher than at 0 hours. On the other hand, HAS3 mRNA expression gradually increased over time after injury, ~3-fold at 2 hours, ~1.7-fold at 4 hours, and ~4-fold at 8 hours compared to 0 hour (Fig. 2C). HAS2 mRNA expression decreased at 2 hours by 50%, returning to original levels at 4 hours, and dropping again to 50% at 8 hours (Fig. 2B). Interestingly, the two drops in HAS2 mRNA expression coincided with the major peaks of HAS1 mRNA (2 hours) and HAS3 mRNA (8 hours) expressions, respectively. Thus, HAS2 mRNA expression seemed to follow a compensatory mechanism after injury, where its expression was decreased when HAS1 mRNA and HAS3 mRNA expressions were elevated. These results indicated that all the HASs may be required for maintaining the corneal epithelium and also after injury. Thus, to establish the role of HA in the LSC niche in the cornea, we obtained transgenic strains for the three different HASs. Given that TSG-6 catalyzes the transfer of HCs to the HA chains forming a HC-HA/TSG-6 matrix in injured tissues, we also obtained HA Regulates LSC Differentiation

**Role of HA and TSG-6 in Corneal Inflammation**

TSG-6 and HA matrices have a well-established role in inflammation; therefore, the effect of HA and TSG-6 on the infiltration and resolution of inflammatory responses was analyzed using alkali burn in HAS1−/−:HAS3−/−, HAS2−/−:CorEpi, TSG-6−/−, and wild-type mice. Corneal integrity and the inflammatory response were evaluated 2 weeks after alkali burn. At this time, wild-type mice presented a fully healed corneal epithelium with ~7 to 8 cell layers, whereas HAS1−/−:HAS3−/− and HAS2−/−:CorEpi mice presented disorganized corneal epithelial layers, making it difficult to evaluate the number of cell layers (Fig. 4A). Moreover, HAS1−/−:HAS3−/− and HAS2−/−:CorEpi basal cells presented a loss of the columnar morphology (Fig. 4A). Interestingly, Periodic-Schiff staining revealed that HAS2−/−:CorEpi mice present primarily goblet cells in the peripheral cornea (Figs. 4B, 4C) and a few goblet cells in the central cornea (Fig. 4D). HAS2−/−:CorEpi mice also presented macrophages in the central and peripheral corneas detected by anti-F4/80 and anti-Iba1 staining (Figs. 4E, 4F, respectively). The corneal epithelium of TSG-6−/− mice appeared to be thinner than that of wild-type mice, and there was slight disorganization of the epithelial cell layers; however, this was not as significant as that seen with HAS1−/−:HAS3−/− and HAS2−/−:CorEpi mice. The ultrastructure of the corneas 2 weeks after alkali burn was also analyzed by electron microscopy, and images of the basal and superficial cells were shown (Fig. 5). The ultrastructure of the wild-type alkali burn–treated cornea resembled that of the uninjured cornea (Fig. 3). Therefore, these corneas have fully healed from the alkali burn (Fig. 5). However, there were significant changes in the morphology of HAS1−/−:HAS3−/− and HAS2−/−:CorEpi mouse corneas. Limited adhesion complexes were found between the basal epithelial cells and the basement membrane of HAS1−/−:HAS3−/− mice (Fig. 5).
Moreover, the epithelial cells of these mice were unable to form strong cell-cell and cell-matrix adhesion complexes, and after electron microscopy processing there were significant gaps between the epithelial cells and between the epithelial cells and the basement membrane (black arrows, Fig. 5). HAS2DCorEpi mice presented basal cells with an uneven cell shape, and the cell membranes presented ridges throughout the corneal epithelium. The HAS2DCorEpi basal cells presented deep ridges (white and black arrows in Fig. 5, Supplementary Fig. S2). The reduction in the number of epithelial layers in the corneas of HAS1/C0/C0;HAS3/C0/C0 and HAS2DCorEpi mice was also evident through electron microscopy analysis. Electron microscopy data suggested that HAS1/C0/C0;HAS3/C0/C0 and HAS2DCorEpi mice lacked epithelial basal cells and had a reduced number of squamous cell layers when compared with wild-type mice (Fig. 5).

**Figure 4.** Histological analysis of HAS1−/−;HAS3−/−, HAS2Δ/ΔCorEpi, TSG-6−/−, and wild-type mouse corneas after alkali burn. Sections from corneas of HAS1−/−;HAS3−/−, HAS2Δ/ΔCorEpi, TSG-6−/− and wild-type mice 2 weeks after an alkali burn were stained with H&E. Images are from the central cornea of all mice (A) and from the peripheral cornea of HAS2Δ/ΔCorEpi mice (B). HAS1−/−;HAS3−/− and HAS2Δ/ΔCorEpi mice show unorganized corneal epithelium, and HAS2Δ/ΔCorEpi mice present inflammatory cells within the corneal stroma. Sections from HAS2Δ/ΔCorEpi mice 2 weeks after alkali burn were also stained with Periodic-Schiff, revealing goblet cells (pink) in the peripheral cornea (C) and central cornea (D). Sections from HAS2Δ/ΔCorEpi mice 2 weeks after alkali burn were stained with anti-F4/80 (green), Iba1 (red), and DAPI (blue) in the central cornea (E) and peripheral cornea (F). Scale bars: 50 μm.

**Figure 5.** The ultra-structure of HAS1−/−;HAS3−/−, HAS2Δ/ΔCorEpi, TSG-6−/−, and wild-type mouse corneas 2 weeks after alkali burn. The ultra-structure of corneas from HAS1−/−;HAS3−/−, HAS2Δ/ΔCorEpi, TSG-6−/−, and wild-type mice were analyzed by electron microscopy 2 weeks after alkali burn. HAS1−/−;HAS3−/− mice show disrupted cell-cell and cell-basement membrane adhesion complexes, which are clearly seen in control and TSG-6−/− mice (white arrows). Moreover, HAS1−/−;HAS3−/− epithelial cells are unable to form strong cell-cell and cell-matrix adhesion complexes, and after electron microscopy processing there are significant gaps between the epithelial cells and between the epithelial cells and basement membrane (black arrows). HAS2Δ/ΔCorEpi mice basal cells have an uneven cell shape, and the membranes present ridges (black and white arrows). Scale bars: 2 μm.
Hyaluronan Rich Limbal Stem Cell (LSC) Niche

Our data demonstrated that there was an intricate regulation of HAS expression in the corneal LSC niche after injury. To verify the expression profile of HA in the cornea, we localized HA in the corneas of wild-type, HAS1−/−; HAS3−/−, HAS2−/−CorEpi, and TSG-6−/− mice with the HA binding protein. Interestingly, wild-type corneal staining revealed that HA was specifically expressed in the limbal region, potentially comprising an HA rich limbal stem cell niche (Fig. 7). HAS1−/−; HAS3−/− mice presented a loss of HA expression in the limbal region (Fig. 7). Thus, we could infer that HAS1 and/or HAS3 are necessary for maintaining the limbal stem cell niche. HAS2−/−CorEpi induced at P7 and P21 also presented a loss of HA in the LSC niche, whereas corneal inflammation persisted in maintenance of the inflammatory response by 2 weeks after alkali burn. Interestingly, wild-type mice were identified as K12+ cells in the cornea 2 weeks after alkali burn, which, as mentioned previously, were identified as goblet cells (Fig. 4). TSG-6−/− mice presented an increase in HA expression 2 weeks after alkali burn that was also no longer restricted to the limbal region, but present in the epithelium of the peripheral cornea (Fig. 7B).

Epithelial and Limbal Stem Cell Markers

Our findings suggest that corneal LSCs secrete an HA rich niche. To establish whether the HA within the limbal stem cell niche has a role in maintaining the limbal stem cells in their multipotent state, we analyzed the expression profile of LSCs (keratin 15, K15+ cells) and of differentiated epithelial cells (keratin 12, K12+ cells) in the corneas before and after alkali burn in the HA LSC niche and throughout the corneas of HAS1−/−; HAS3−/−, HAS2−/−CorEpi, and TSG-6−/− mice. In the uninjured corneas, no obvious differences in K12+ cell expression were observed in TSG-6−/− mice when compared with wild-type mice. However, HAS2−/−CorEpi induced at P7 presented K12+ cells in the limbus, and no K15+ cells, thus the loss of HA due to the ablation of HAS2 could lead to limbal stem cell deficiency in HAS2−/−CorEpi induced at P7 or earlier (Fig. 8). On the other hand, HAS1−/−; HAS3−/−, and HAS2−/−CorEpi mice induced at P21 presented an increase in...
FIGURE 6. Analysis of corneal integrity and inflammation after injury. HAS1\textsuperscript{-/-};HAS3\textsuperscript{-/-}, HAS2\textsuperscript{D/D}CorEp\textsuperscript{i}, and wild-type mice were subjected to alkali burn and 2 weeks later analyzed using a stereomicroscope. Images were captured using a white light (A, top). To assess corneal integrity, fluorescein was placed on the ocular surface, and subsequently the eye was washed and the cornea imaged under a fluorescent stereomicroscope (A, bottom). Whole-mount staining for F4/80\textsuperscript{+} cells and SMA\textsuperscript{a} was done on corneas of HAS1\textsuperscript{-/-};HAS3\textsuperscript{-/-}, HAS2\textsuperscript{D/D}CorEp\textsuperscript{i}, TSG-6\textsuperscript{-/-}, and wild-type mice 2 weeks after alkali burn. The numbers of F4/80\textsuperscript{+} cells and SMA\textsuperscript{a} cells were counted in a blinded manner (B, C, respectively). Corneal haze and inflammation in HAS1\textsuperscript{-/-};HAS3\textsuperscript{-/-}, HAS2\textsuperscript{D/D}CorEp\textsuperscript{i}, TSG-6\textsuperscript{-/-}, and wild-type mice were assessed by in vivo confocal microscopy (D). The corneal epithelial morphology 2 weeks after alkali burn was assessed by in vivo confocal microscopy (E).
K15⁺ cells into the peripheral cornea, which was more significant in the HAS1⁻/⁻, HAS3⁻/⁻, HAS2ΔΔCorEpi, TSG-6⁻/⁻, and wild-type mice. HA (red) and K14 (green) were stained in uninjured (A) and alkali burnt (B) corneas of HAS1⁻/⁻, HAS3⁻/⁻, HAS2ΔΔCorEpi, TSG-6⁻/⁻, and wild-type mice and images captured of the limbal region (Limbus) and central cornea (Central). The TSG-6⁻/⁻ and wild-type mice show HA staining in the corneal limbus, whereas HAS1⁻/⁻, HAS3⁻/⁻, and HAS2ΔΔCorEpi (induced at P21 and P7) mice lack HA staining in the limbus. Two weeks after alkali burn, TSG-6⁻/⁻ mice present an increase in HA expression into the peripheral cornea, HAS1⁻/⁻, HAS3⁻/⁻, and HAS2ΔΔCorEpi (induced at P21 and P7) mice express HA throughout the entire cornea, whereas wild-type mice present no changes in HA expression after injury. The dashed line (lower right image) shows the division between epithelial cells and the stroma and the asterisks mark where epithelial cells are growing into the stroma. Scale bar: 20 μm.

Figure 7. Expression profiles of HA and K14 in the corneas of HAS1⁻/⁻, HAS3⁻/⁻, HAS2ΔΔCorEpi, TSG-6⁻/⁻, and wild-type mice. HA (red) and K14 (green) were stained in uninjured (A) and alkali burnt (B) corneas of HAS1⁻/⁻, HAS3⁻/⁻, HAS2ΔΔCorEpi (induced at P21 and P7), TSG-6⁻/⁻, and wild-type mice and images captured of the limbal region (Limbus) and central cornea (Central). The TSG-6⁻/⁻ and wild-type mice show HA staining in the corneal limbus, whereas HAS1⁻/⁻, HAS3⁻/⁻, and HAS2ΔΔCorEpi (induced at P21 and P7) mice lack HA staining in the limbus. The dashed line (lower right image) shows the division between epithelial cells and the stroma and the asterisks mark where epithelial cells are growing into the stroma. Scale bar: 20 μm.

**Ex Vivo Debridement Wounding of Corneas From HAS1⁻/⁻, HAS3⁻/⁻, HAS2ΔΔCorEpi, and Wild-Type Mice**

To evaluate the role of HA on corneal healing without the influence of inflammatory cell infiltration, we analyzed ex vivo debridement wounds. For such, the corneas were injured, eyeballs enucleated, and the corneas allowed to heal for 24 hours in explant culture conditions. The size of the wound area was measured as the fluorescein positive area at 0, 6, 12, and 24 hours after injury. Six hours after the debridement wound, HAS1⁻/⁻, HAS3⁻/⁻, and HAS2ΔΔCorEpi mice displayed a slight increase in the wounded area when compared with 0 hours due to a receding wound edge (Fig. 9A). This could be due to the eventual cell death or desquamation of cells that were damaged during the injury or in close proximity to the wounded area. The wounded area did not significantly change in HAS2ΔΔCorEpi mice by 6 hours after the debridement wound.
On the other hand, wild-type mice presented a 15% decrease in the wounded area 6 hours after the debridement wound (Fig. 9A). Twelve hours after the debridement wound, all wild-type mice displayed a significant reduction in the wounded area when compared with both 0 and 6 hours, with a mean wounded area of 68% when compared with 0 hours (Fig. 9A). In contrast, for HAS1−/−:HAS3−/− mice the wound edges receded further at 12 hours after injury, and 11 of the 14 HAS1−/−:HAS3−/− mice presented increases in wounded area, with a mean wounded area of 108% when compared with 0 hours (Fig. 9A). HAS2 CorEpi mice presented no changes in the wounded area 12 hours after debridement wound. Twenty-four hours after the debridement wound, all mice presented significant reductions in the wounded area; however, the wounded areas in HAS1−/−:HAS3−/− and HAS2 CorEpi mice were significantly larger than in wild-type mice, with wounded areas at ~82%, ~78%, and ~17%, respectively (Fig. 9A). Therefore, HAS1−/−:HAS3−/− and HAS2 CorEpi mice clearly displayed delayed wound healing when compared to wild-type mice.

The eyeballs were processed for histology 24 hours after the debridement wound. HAS1−/−:HAS3−/− mice presented an accumulation of epithelial cells at the wound edge, which could be due to an inability of the epithelial cells to migrate along the basement membrane (Fig. 9B). This would be consistent with the findings that HAS1−/−:HAS3−/− mice present reduced adhesion complexes between the epithelial cells and the basement membrane. On the other hand, HAS2 CorEpi mice presented a reduction of corneal epithelial cell layers, indicating that these mice could present reduced cell proliferation, which would culminate in the delayed wound healing (Fig. 9B). Neither the wild-type, HAS1−/−:HAS3−/−, nor HAS2 CorEpi mice presented HA staining at the wound edge (Fig. 9C). However, HAS1−/−:HAS3−/− presented an increase in K15+ cells in the corneal limbus, whereas in contrast HAS2 CorEpi mice presented a decrease in the number

**Figure 8.** Expression profiles of K12 and K15 cells in the cornea of HAS1−/−:HAS3−/−, HAS2 CorEpi, TSG-6−/−, and wild-type mice. K12 (green) and K15 (red) cells were stained in uninjured (A) and alkali burnt (B) corneas of HAS1−/−:HAS3−/−, HAS2 CorEpi (induced at P21 and P7), TSG-6−/−, and wild-type mice and images captured of the limbal region (Limbus) and central cornea (Central). HAS2 CorEpi (induced at P21), TSG-6−/−, and wild-type mice present K15+ cells exclusively in the corneal limbus in uninjured corneas. HAS1−/−:HAS3−/− mice present an increase in K15+ cells into the peripheral cornea, and in contrast HAS2 CorEpi (induced at P7) lack K15+ cells in the corneal limbus. Two weeks after alkali burn, HAS1−/−:HAS3−/− and HAS2 CorEpi (induced at P21 and P7) mice present K15+ cells throughout the cornea and in turn lack K12+ cells. The dashed line (lower right image) shows the division between epithelial cells and the stroma. Scale bar: 20 µm.
DISCUSSION

Hyaluronan is a ubiquitous component of the extracellular matrix that is enriched during the early stages of development and disease, and recent studies have demonstrated that HA matrices have an important role in the stem cell niche. We have demonstrated that human umbilical cord mesenchymal stem cells secrete a specific HA/HC/TSG-6/PTX3/versican glycosylceramide that enables these cells to survive xenograft rejection increasing their engraftment success. Following our work, TSG-6, HA and exogenous Ixl were shown to increase embryonic MSC engraftment into skeletal muscle and favor differentiation into muscle cells. The authors speculated that TSG-6, HA, and Ixl were assembling into a glycocalyx that favored MSC engraftment. This group went on to show that TSG-6, HA, and Ixl assemble to form a microenvironment necessary for successful MSC engraftment and that enables the subsequent differentiation of MSCs. We hereby show that HA is also a vital component of the corneal LSC niche.

The size of the HA chains has an important role during matrix assembly, composition, and function. Studies have shown that primarily two forms of HA exist: HMWHA of approximately 2,000 kDa and LMWHA of approximately 200 kDa. HA chains are synthesized by HAS1, HAS2, or...
HAS5; however, a basic understanding on how HAS enzymes regulate the length of the growing HA chain during the biosynthetic process, which greatly affects its physiological function, remains unknown. It has also been speculated that HAS1 and HAS5 produce primarily HMWHA, whereas HAS2 produces primarily LMWHA. Interestingly, naked mole rats (Heterocephalus glaber) fibroblasts have been shown to secrete extremely high-molecular-weight hyaluronan, more than five times larger than that found in other mammals, including humans. This extremely high-molecular-weight hyaluronan contributes to the exceptionally high longevity and unusual resistance to cancer displayed by naked mole rats.71-76 The different HAS enzymes present a specific special-function, including humans. This extremely high-molecular-weight hyaluronan was fully healed at 2 weeks after injury and no longer secrete extremely high-molecular-weight hyaluronan, more than five times larger than that found in other mammals.

To elucidate the role of the different HAS enzymes in maintaining the HA matrix in the LSC niche, we used knockout mice for the different HAS enzymes. HAS2 is the most widely distributed HAS in tissues, thus the HAS2 null mouse is embryonic lethal. Therefore, we generated a conditional knock-out mouse model to remove HAS2 from K14+ cells, which would include corneal LSCs and corneal epithelial cells. Curiously, both HAS1-/Dm and HAS2-/Dm mice presented a loss of HA in the LSC niche. The loss of HA in the LSC niche did not lead to corneal dysgeneisy in any of the uninjured HAS1-/Dm;HAS3+/Dm or HAS2-/CorEpi mice, indicating that epithelial cell proliferation is sufficient to maintain a stratified epithelium in unchallenged corneas. The corneal epithelium is a continuously regenerating tissue maintained by basal cells that undergo mitosis, and dividing cells move upward to replenish wing cells.78,79 As the new cells move upward, superficial squamous cells slough off. Corneal LSCs are highly proliferative undifferentiated cells that provide an unlimited supply of proliferating cells to replenish corneal epithelial cells after injury.9,80 Therefore, our results support the hypothesis that unchallenged corneas are maintained primarily by basal epithelial cells. Previous studies have reported that the vertical turnover of the corneal stratified epithelium in mammals ranges from 7 to 14 days and suggest that limbal stem cells are necessary for long-term renewal of the epithelium.81 However, the Tseng group have elegantly shown that the corneal epithelium can self-sustain in the absence of the corneal limbus up until the point that the epithelium is perturbed.82 Majo et al.83 have also shown that limbal stem cells solely migrate from the limbus onto the cornea after injury. This study also demonstrated that catarization of the entire limbal circumference, which would destroy both limbal stem cells and the limbal stem cell niche, does not lead to impaired vision.85 Our data further reinforce the notion that limbal stem cells are not required for maintaining the corneal epithelium during homeostasis. HAS1-/Dm;HAS3+/Dm and HAS2-/CorEpi mice showed impaired wound healing after both ex vivo debridement and alkali burn. The ex vivo debridement wound model was used to study the effect of HA in the LSC niche on wound healing without the influence of infiltrating inflammatory cells. The alkali burn model was used to evaluate the role of HA in the LSC niche on cornea regeneration and inflammation. Our alkali burn model spares the LSCs, and wild-type mouse corneas were fully healed at 2 weeks after injury and no longer presented signs of inflammatory response. On the other hand, HAS1-/Dm;HAS3+/Dm mice and HAS2-/CorEpi mice and mice showed increased inflammatory response and failure to form a stratified epithelium after injury.

We also investigated whether HA in the LSC niche could have a role in regulating LSC specification. For such, we stained for LSCs (K15+ cells) and differentiated corneal epithelial cells (K12+ cells) in HAS1-/Dm;HAS3+/Dm and HAS2-/CorEpi mice. Interestingly, HAS2-/CorEpi mice induced at 7 days presented a loss of LSCs in the corneal limbus, indicating that the loss of HAS2 leads to LSCD. Moreover, HAS2-/CorEpi mice presented primarily goblet cells in the peripheral cornea and sparse goblet cells in the central cornea after alkali burn. A hallmark of LSCD is conjunctivization of the cornea, which is the invasion of conjunctival surface cells (goblet cells) onto the corneal surface.5,26 Therefore, the presence of goblet cells in the corneal epithelium after injury further supports the notion that the loss of HAS2 leads to LSCD. Taken together, our results indicate that HAS2-/CorEpi mice could be a useful model for studying LSCD. Curiously, after injury, both HAS1+/Dm;HAS3-/Dm and HAS2-/CorEpi mice presented an increase in HA expression, which, after alkali burn, is present throughout the cornea. Therefore, HAS1+/Dm;HAS3-/Dm mice up-regulate HAS2 as a compensatory mechanism after injury, whereas HAS2-/CorEpi mice up-regulate HAS1 and/or HAS3 expression after injury. The change in HA distribution in the cornea from being located solely in the corneal limbus to being expressed throughout the corneal epithelium in turn alters the distribution of LSCs. Interestingly, the change in HA distribution leads to the presence of LSCs throughout the corneal epithelium and the absence of differentiated corneal epithelial cells. These data indicate that the HA microenvironment maintains the LSC phenotype. Thus, as LSCs migrate out of the LSC niche, the lack of an HA environment could trigger their differentiation into corneal epithelial cells. Curiously, HAS2-/CorEpi mice induced at 7 days both HA and LSCs (K15+ cells) in the corneal limbus and instead presented corneal epithelial cells (K12+ cells); however, after injury these mice were able to switch from solely K12+ cells to K15+ cells. How mice lacking LSCs were able to generate de novo LSCs remains to be determined. Previous studies have demonstrated that corneal epithelial cells have high regenerative and migratory potential.83,84 Moreover, Majo et al.85 were also able to show that corneal epithelial cells could assume either a conjunctival or epithelial cell phenotype depending on the site of transplantation; however, these findings have been met with some controversy. Our data show that the K12+ to K15+ cell switch coincides with the up-regulation of HA, further indicating that HA could regulate LSC and corneal epithelial specification. Therefore, the up-regulation of HA synthesis within the corneal limbus could provide a viable therapeutic approach for treating LSCD. Whether the ultrastructure and composition of the HA matrix and length of the HA chains present throughout the cornea in HAS1+/Dm;HAS3-/Dm and HAS2-/CorEpi mice after injury are similar to the HA found in the healthy LSC niche remains to be elucidated. TSG-6-/Dm mice showed altered HA expression in the LSC niche and increased inflammation after alkali burn. In the TSG-6-/Dm mice the absence of TSG-6 could potentially lead to a less compact/stable HA matrix, which could affect the migration of LSCs and inflammatory cells. Therefore, our data indicate that potentially a specialized HC-HA/TSG-6 matrix could be present in the corneal LSC niche; however, further research is necessary to fully characterize the composition of this matrix. Amniotic membrane based therapies for treating LSCD have been studied for many years.50,51,56,85,86 The Tseng group have determined that a HCA/PTX3 complex is the pharmacologically active component of the amniotic membrane commonly used for treating ocular surface disorders, including LSCD.26 Substantial studies have demonstrated that HCA/PTX3 complexes attain powerful anti-inflammatory properties, and this complex was hypothesized to improve the outcome of LSCD patients by suppressing the inflamma-
tory response. Our data indicate that the therapeutic properties of the amniotic membrane could go beyond simply suppressing inflammation. The HC-HA/TSG-6 complex released by the amniotic membrane could provide support to LSCs forming a transient LSC niche for any residual LSCs.

Corneal injury that leads to substantial damage to LSCs or the LSC niche decreases the number of LSCs and thereby reduces the ability of these cells to resurface the corneal epithelium. A significant loss of LSCs or the LSC niche leads to LSCD. LSCD patients present recurring erosions, corneal inflammation, severe pain, and eventual conjunctivalization of the cornea. TSG-6 and HA matrices have a well-established role in inflammation; assembly of the HC-HA/TSG-6 matrix has been shown to be immunosuppressive, protecting tissues from the detrimental effects of inflammation. Therefore, damage to the LSC niche and consequently the loss of this HA specific environment in the cornea/conjunctiva zone could be in part responsible for the increase in inflammatory cell infiltration in LSCD patients. Moreover, evidence suggests that the limbus may contain essential cues to limit the migration of conjunctival cells into the cornea, thereby precluding conjunctivalization in a normal cornea. Our data show that HAS2ACorePep mice present goblet cell invasion into the peripheral and central cornea. LSCD patients eventually present conjunctivalization, which in turn leads to severe vision loss. Because LSCD involves the loss of both LSCs and the LSC niche, we could hypothesize that the loss of the HA-specific LSC niche could be in part responsible for the migration of conjunctival cells onto the cornea in LSCD patients. Currently, the largest hurdle in developing limbal stem cell transplantation is the efficient expansion of donor limbal stem cells ex vivo prior to transplantation. Our work clearly demonstrates that HA is essential for maintaining the LSC phenotype.

This study identified a HA specific matrix present in the cornea exclusively in the LSC niche. The disruption of this HA matrix within the LSC niche leads to increased inflammatory response after injury and altered LSC and corneal epithelial cell specification. Follow-up work will aim to characterize the precise structural composition of this HA matrix and identify the precise length of the HA chains present in the LSC niche.

Acknowledgments

The authors dedicate this work to the remembrance of Mark Lauer. The authors thank Kazadi Nadine Mutoji for her invaluable technical assistance, Naoki Itano for kindly providing HAS1 null mice, and Winston Kao for kindly providing the K14 rtta and tet-O-core mice. They also thank the Department of Ophthalmology from the University of Cincinnati for their support during the transition to Houston.

Presented in part at the annual meeting of the Association for Research in Vision and Ophthalmology, Baltimore, Maryland, United States, May 2017.

Supported by start-up funds from the University of Houston, The Mizutani Foundation, and the National Institutes of Health/National Eye Institute Core Grant P30 EY07551.
