Abstract Recently a gauged two Higgs doublet model, in which the two Higgs doublets are embedded into the fundamental representation of an extra local $SU(2)_H$ group, was constructed. Both the new gauge bosons $Z'$ and $W'^{(p,m)}$ are electrically neutral. While $Z'$ can be singly produced at colliders, $W'^{(p,m)}$, which is heavier, must be pair produced. We explore the constraints of $Z'$ using the current Drell–Yan type data from the Large Hadron Collider. Anticipating optimistically that $Z'$ can be discovered via the clean Drell–Yan type signals at a high luminosity upgrade of the collider, we explore the detectability of extra heavy fermions in the model via the two leptons/jets plus missing transverse energy signals from the exotic decay modes of $Z'$. For the $W'^{(p,m)}$ pair production in a future 100 TeV proton–proton collider, we demonstrate certain kinematical distributions for the two/four leptons plus missing energy signals that feature distinguishable from the Standard Model background. In addition, comparisons of these kinematical distributions between the gauged two Higgs doublet model and the littlest Higgs model with T-parity, the latter of which can give rise to the same signals with competitive if not larger cross sections, are also presented.

1 Introduction

With the discovery of the 125 GeV scalar boson at the Large Hadron Collider (LHC), the Standard Model (SM) with just one Higgs doublet has now been generally accepted as the standard theory or framework to describe the fundamental strong and electroweak interactions for three generations of elementary particles of quarks and leptons. An extended Higgs sector, however, is often used to address various theoretical puzzles like the neutrino masses, dark matter (DM), the matter– antimatter asymmetry, and the hierarchy problem, which remain unexplained in this standard framework. Perhaps the general two Higgs doublet model (2HDM), in particular in the context of supersymmetric theories, is studied most in the literature. Due to its diverse variations, 2HDM has been used as a prototype to address the aforementioned theoretical issues. For reviews of 2HDM and its supersymmetry version, see for example [1–4]. One of the interesting 2HDM variants is the inert Higgs doublet model [5–8], in which the neutral component of the second Higgs doublet can be a dark matter candidate due to a discrete $Z_2$ symmetry imposed on the scalar potential. Detailed analysis for the inert Higgs doublet model can be found for example in [9–12]. The origin of multiple inert Higgs doublets in the context of grand unification has been addressed in [13].

In a recent work [14], we have proposed a novel model, dubbed the Gauged Two Higgs Doublet Model (G2HDM), where the two Higgs doublets $H_1$ and $H_2$ in 2HDM are embedded into a doublet $H = (H_1, H_2)^T$ of a new non-abelian $SU(2)_H$ gauge group. The SM $SU(2)_L$ right-handed singlet fermions are paired up with new fermions to form $SU(2)_H$ doublets, whereas $SU(2)_L$ left-handed doublet fermions are singlets under the $SU(2)_H$. Four additional chiral (left-handed) fermions for each generation, all singlets under both $SU(2)_L$ and $SU(2)_H$, are also introduced to render the model free of gauge anomalies. In this model, an inert Higgs doublet can be naturally realized without imposing the ad hoc $Z_2$ symmetry mentioned above to accommodate a DM candidate. Flavor changing neutral currents naturally are also absent at tree level. We note that it is widely believed that global symmetry (whether it is discrete or continuous) may be strongly violated by gravitational effects [15,16]. Thus from an effective field theory point of view it is desirable to embed discrete symmetries into local gauge symmetries below the Planck scale [15]. Indeed, besides $Z_2$, non-abelian discrete flavor groups like $\{A_4, S_4, A_5\}$, $\{Q_6, T', O', I'\}$, and

a e-mail: timluyu@hotmail.com
$\{T_1, \Delta(27), PSL(2, 7)\}$ can be minimally embedded into $SO(3)$, $SU(2)$, and $SU(3)$, respectively [17].

In G2HDM, a distinctive feature is all the $SU(2)_H$ gauge bosons $Z'$ and $W'(p,m)$ are electrically neutral which is not the case for the Left–Right Symmetry Model (LRSM) [18, 19], the Littlest Higgs Model with T-parity (LHT) [20–22], and the original Twin Higgs Model (THM) [23,24]. Naturally one might ask: how do we distinguish the G2HDM $Z'$ and $W'(p,m)$ from other gauge boson impostors which also arise from the non-abelian group $SU(2)$? In terms of collider searches, some of the new gauge bosons from the aforementioned models can never be singly produced due to the gauge symmetry involved. For instance, the $W'(p,m)$ in G2HDM and $W^\pm_H$ in LHT may not be singly produced at the LHC. Generally speaking, the $Z'$ and $W'(p,m)$ as well as their impostors are short-lived and it is not possible to identify the new gauge bosons using the tracking or displaced vertex techniques designed for long-lived particles. Hence, in addition to their production cross sections, detailed kinematics distributions have to be involved for making the differentiation.

If new gauge bosons can be singly produced, they will be stringently constrained by exotic searches from the LHC [25,26] due to large (resonant) production cross sections. The latest LHC 13 TeV $Z'$ resonance searches based on the channels of dilepton [27,28], dijet [25,29], $b$-quark pair [30], $t$-quark pair [31], and other bosonic final states [32–34] have recently been released. Among these searches, the cleanest dilepton channels yield the most strong constraint on the $Z'$ coupling to SM fermions in the light of the small background. Moreover, from the total electric charge of the decay products it is straightforward to tell singly produced charged bosons from neutral ones.

| Matter fields | $SU(3)_C$ | $SU(2)_L$ | $SU(2)_H$ | $U(1)_Y$ | $U(1)_X$ |
|-------------|----------|----------|----------|---------|---------|
| $H = (H_1, H_2)^T$ | 1        | 2        | 2        | 1/2     | 1       |
| $\Phi_H = (\Phi_1, \Phi_2)^T$ | 1        | 1        | 2        | 0       | 1       |
| $\Delta_H = \left( \frac{\Delta_1/2}{\sqrt{2}} \begin{pmatrix} \Delta_p/\sqrt{2} & \Delta_m/\sqrt{2} \end{pmatrix} \right)$ | 1        | 1        | 3        | 0       | 0       |
| $Q_L = (u_L, d_L)^T$ | 3        | 2        | 1        | 1/6     | 0       |
| $U_R = (u_R, u_R)^T$ | 3        | 1        | 2        | 2/3     | 1       |
| $D_R = (d_R, d_R)^T$ | 3        | 1        | 2        | -1/3    | -1      |
| $u_L^H$ | 3        | 1        | 1        | -1/3    | 0       |
| $d_L^H$ | 1        | 2        | 1        | -1/2    | 0       |
| $L_L = (v_L, e_L)^T$ | 1        | 1        | 2        | 0       | 1       |
| $N_R = (v_R, v_R)^T$ | 1        | 2        | 1        | 0       | 0       |
| $E_R = (e_R^H, e_R)^T$ | 1        | 1        | 2        | -1      | -1      |
| $v_L^H$ | 1        | 1        | 1        | 0       | 0       |
| $e_L^H$ | 1        | 1        | 1        | -1      | 0       |

The current bound from the LHC dilepton searches [27, 28] for $Z_R$ in the minimal LRSM, assuming $m_{Z_R} = 1.7 m_{W_R}$ and $g_L = g_R$, is $m_{Z'} > 3.2$ TeV [35]. Similarly for $Z'$ and $W'$ in the Left–Right THM (LRTH) [36] with $m_{W'} = m_{Z'} \sqrt{\cos 2\beta_{w}/\cos \theta_{w}}$ and $g_L = g_R$, one obtains the limit $m_{Z'} > 3.36$ TeV. In some variants of the THM (see e.g. Ref. [37]), where the $SU(2)$ symmetry is doubled and the $U(1)$ symmetry of the twin sector becomes a global symmetry, the exotic $W$ boson can only be doubly produced. In this case, the exotic $W$ might behave similarly to $W'(p,m)$ in G2HDM in terms of collider signatures. To distinguish them, one will need more information such as the new scalar and fermion mass spectra, which are quite different in the two models.

Suppose a new $Z'$ is observed via resonance searches at the LHC. We would like to know if this new $Z'$ belongs to a new abelian $U(1)$ or a member of a new $SU(2)$. In order to confirm the existence of G2HDM, the next step is to discover the neutral $W'(p,m)$. In G2HDM, unlike $Z'$, the $W'(p,m)$ do not couple bilinearly to the SM quarks. Thus $Z'$ can be singly produced via quark–antiquark annihilations while $W'(p,m)$ must be pair produced via exchange of new heavy fermions or $Z'$. For $W'(p,m)$ produced in pairs, more information like detailed kinematical distributions other than the production cross sections have to be involved so as to make distinguishable signatures from say the $W^\pm_H$ pair in LHT.

Besides the new gauge bosons, in order to give masses to all fermions the scalar sector is also enlarged beyond the two Higgs doublets with one extra doublet $\Phi_H$ and one extra triplet $\Delta_H$ of $SU(2)_H$, both of which are singlets under $SU(2)_L$. The particle content of the G2HDM [14] is summarized in Table 1 together with their quantum numbers.
In this work, we will focus on two benchmark mass spectra (Spectrum A and Spectrum B) of the G2HDM for our collider studies. Spectrum A contains heavy and decoupled new quarks, while Spectrum B comprises relatively light new quarks. For all scenarios, new leptons are assumed to be lighter than the additional gauge bosons of interest. Due to the fact $Z'$ couples to SM quarks and can be singly produced at the LHC, we first update the bounds on the $SU(2)_H$ gauge coupling $g_H$ as a function of the $Z'$ mass $m_{Z'}$ by using the newly released results of the dilepton and dijet searches from the LHC. Next, $Z'$ exotic decays into new heavy fermions followed by decays into SM fermions are investigated at the 14 TeV High Luminosity LHC (HL-LHC) and bounds from LHC searches on supersymmetric particles can be applied with simplified assumptions. Then, for the neutral $SU(2)_H$ gauge group, we first update the bounds on the $SU(2)_H$ doublet $H_2$ does not obtain a vev and its neutral component could be the DM candidate. As shown in [14], DM stability is protected by the $SU(2)_H$ symmetry and Lorentz invariance. In other words, an inert Higgs doublet $H_2$ emerges naturally in G2HDM without resorting to the discrete $Z_2$ symmetry.¹ We specify the most general and renormalizable scalar potential invariant under $SU(2)_L \times U(1)_Y \times SU(2)_H \times U(1)_X$ in Appendix A and in turn discuss the scalar mass spectra in Appendix B.

To generate masses for the SM fermions via Yukawa couplings in an $SU(2)_H$ invariant manner, we choose to pair SM right-handed fermions with new right-handed ones into $SU(2)_H$ doublets, whereas the SM left-handed fermions are singlets under $SU(2)_H$ as indicated in Table 1. In addition, to make all new fermions massive via the vev of the $SU(2)_H$ doublet $\Phi_H = (\Phi_1, \Phi_2)^T$, extra left-handed fields $\tilde{f}^H_L$ ($f = d, u, e, \nu$) are introduced. The corresponding $SU(2)_H$ invariant Yukawa couplings are

$$L_{\text{Yuk}} \supset -\bar{y}_d d_L^T (d^H_R \Phi_2 - d_R \Phi_1) - \bar{y}_u u_L^T (u_R \Phi^*_1 + u^H_R \Phi^*_2) - \bar{y}_e e_L^T (e^H_R \Phi_2 - e_R \Phi_1) - \bar{y}_\nu \nu_L^T (\nu_R \Phi^*_1 + \nu^H_R \Phi^*_2) + \text{H.c.}$$  

(1)

With a non-vanishing $\langle \Phi_2 \rangle$, the four Dirac fields $d^H, u^H, e^H, \nu^H$ acquire a mass of $\bar{y}_d \langle \Phi_2 \rangle, \bar{y}_u \langle \Phi_2 \rangle, \bar{y}_e \langle \Phi_2 \rangle$, and $\bar{y}_\nu \langle \Phi_2 \rangle$, respectively. On the other hand, the SM quarks and leptons obtain their masses from the vev of $H_1$ via the Yukawa couplings,

$$L_{\text{Yuk}} \supset +\bar{y}_d \tilde{Q}_L (d^H_R H_2 - d_R H_1) - \bar{y}_u \tilde{Q}_L (u_R \tilde{H}_1 + u^H_R \tilde{H}_2) + \bar{y}_e \tilde{L}_L (e^H_R H_2 - e_R H_1) - \bar{y}_\nu \tilde{L}_L (\nu_R \tilde{H}_1 + \nu^H_R \tilde{H}_2) + \text{H.c.}$$  

(2)

with $\tilde{H}_{1,2} = i t_2 \tilde{H}_{1,2}^*$. Note that in both Yukawa couplings given in (1) and (2) only the SM Higgs doublet $H_1$ couples bilinearly with the SM fermions. Thus, FCNC interactions for the SM fermions naturally are absent at tree level in G2HDM. It also implies the new heavy fermions can decay into SM fermions plus DM via the Yukawa couplings in (2). For instance, $f^H_R \rightarrow f_L H_2^{0*}$ where $H_2^{0*}$ is a DM candidate and is manifest as the missing transverse energy. We note that the absence of FCNC interactions in 2HDM by embedding the discrete $Z_2$ symmetry into an extra $U(1)'$ has been studied in [40–43].

¹ After symmetry breaking in G2HDM, one can actually show that an effective $Z_2$ symmetry emerges [39].
There are $SU(2)_H$ gauge bosons, $W^{r(p,m)}$ and $W^3$, and the $U(1)_X$ gauge boson $X$, apart from the SM ones. Due to the symmetry breaking pattern, $W^{r(p,m)}$ will not mix with the SM counterparts but $W^3$ and $X$ mix with the SM $SU(2)_L$ $W^3$ and $U(1)_Y$ $Y$ gauge boson. In this setup, besides the SM massless photon corresponding to the unbroken generator $Q = T^2_L + Y$, there exists a massless dark photon corresponding to the unbroken generator $Q_D = 4 \cos^2 \theta_W T^3_L - 4 \sin^2 \theta_W Y + 2 T^3_H + X$. Here $T^2_L (T^3_H)$ is the third generator of $SU(2)_L (SU(2)_H)$, $Y (X)$ is the $U(1)_Y (U(1)_X)$ generator, and $\theta_w$ is the Weinberg angle. Such a massless dark photon could be cosmologically problematic. To circumvent the problem, one can resort to the Stueckelberg mechanism to give a mass to the $U(1)_X$ gauge boson as in [44–47]. One could take this mass to be large enough so that $X$ is decoupled from the particle spectra. Another way out is to treat $U(1)_X$ as a global symmetry as was proposed in [48] and adopted in [14] as well. We will follow the same strategy in what follows.

In this case, after diagonalizing the mass matrix of $Y$, $W^3$ and $W^3$, one obtains massless $Y$, massive $Z$ and $Z'$. Furthermore, the $Z-Z'$ mixing is constrained to be of order $10^{-3}$ for TeV $Z'$ because of the electroweak precision measurements [49]. As a consequence, impacts of the mixing are numerically negligible and will be ignored. The resulting $SU(2)_H$ gauge boson mass spectrum is

$$m_{W^{r(p,m)}}^2 = \frac{1}{4} g_H^2 \left(v^2 + v_\Phi^2 + 4 v_\Delta^2\right),$$

$$m_{Z'}^2 = \frac{1}{4} g_H^2 \left(v^2 + v_\Phi^2\right),$$

(3)

where $(v/\sqrt{2}, v_\Phi/\sqrt{2}, -v_\Delta) = ((H^0_1), (\Phi_2), (\Delta_3))$. Note that $W^{r(p,m)}$ is always heavier than $Z'$ in G2HDM.

As the SM right-handed fermions as well as the new fermions are charged under $SU(2)_H$, they couple to the $W^{r(p,m)}$ and $Z'$ bosons. The relevant gauge interactions without the $Z-Z'$ mixing read

$$\mathcal{L} = \mathcal{L}(W) + \mathcal{L}(\gamma) + \Delta \mathcal{L}.$$  

(4)

Here $\mathcal{L}(W)$ and $\mathcal{L}(\gamma)$ refer to the charged current mediated by the $W$ boson and the electric current by the photon $\gamma$, respectively,

$$\mathcal{L}(W) = \frac{g}{\sqrt{2}} \left(\bar{\nu}_L \gamma \mu e_L + \bar{u}_L \gamma \mu d_L\right) W^\pm_{\mu \nu} + \text{H.c.},$$

$$\mathcal{L}(\gamma) = \sum_f Q_f e \bar{f} \gamma \mu f A_{\mu},$$

(5)

where $Q_f$ is the corresponding fermion electric charge in units of e. $\Delta \mathcal{L}$ represents (electrically) neutral current interactions of the massive bosons, $Z$, $Z'$ and $W^{r(p,m)}$ (for demonstration, only the lepton sector is shown, but it is straightforward to include the quark sector):

$$\Delta \mathcal{L} = \mathcal{L}(Z) + \mathcal{L}(Z') + \mathcal{L}(W^{r(p,m)}),$$

(6)

where

$$\mathcal{L}(Z) = \frac{g}{\cos \theta_W} J^\mu_Z Z_\mu,$$

$$\mathcal{L}(Z') = g H J^\mu_{W',\mu} Z_\mu',$$

$$\mathcal{L}(W^{r(p,m)}) = \frac{1}{\sqrt{2}} g_H \left(J^\mu_{W^{r(p,m)}} W'^{\mu} + \text{H.c.}\right),$$

(7)

and

$$J^\mu_Z = \sum_{f=e,\nu} \left(\bar{f}_L \gamma \mu \nu f L - Q_f \sin^2 \theta_W f L + \bar{f}_R \gamma \mu \nu f R\right),$$

$$J^\mu_{W'} = \sum_{f=R, L} \bar{f}_R \gamma \mu \nu f R \gamma W' R + \bar{f}_R \gamma \mu \nu f R \gamma W' R,$$

(8)

The current interactions in $\mathcal{L}(W^{r(p,m)})$ and $\mathcal{L}(Z')$ will dictate how $W^{r(p,m)}$ and $Z'$ decay into SM and heavy fermions, and they determine which final states one should look into for collider searches.

3 Methodology

To simulate the total cross sections and various distributions for the relevant processes in the colliders, we will follow the standard protocol well established by many collider phenomenologists. We use FeynRules [50] to build up the model files for G2HDM and pass it to Madgraph5 [51] for the matrix element calculation and event generation. We simulate parton showering by using Pythia8.1 [52], and we employ Delphes3 [53] for detector simulations. Finally, the package MadAnalysis5 [54,55] is used to analyze the simulation data.

In the G2HDM, apart from the extra gauge bosons $W^{r(p,m)}$ and $Z'$, additional heavy fermions have to be included to attain gauge invariant Yukawa couplings as explained above. To simplify the analysis, we assume two universal masses for the heavy fermions, one for leptons and the other for quarks. As a result, there are five relevant mass scales in our analysis, namely the masses of the dark matter particle $H^0_1$, the heavy leptons $L^H = (e^H, \mu^H, \tau^H)$ and $\nu^H = (\nu^H_1, \nu^H_2, \nu^H_3)$, the heavy quarks $Q^H = (u^H, d^H, c^H, s^H, t^H, b^H)$, and the two heavy gauge bosons $W^{r(p,m)}$ and $Z'$. In addition, the new charged fermions have to be heavier than 100 GeV, a constraint inferred from the combined analysis of the LEP2 run data by the four LEP collaborations [56]. We will study the
following two benchmark mass spectra for the new fermions, while the new gauge bosons are always assumed to be heavier than 1.5 TeV, so that the gauge coupling $g_H$ is not too small.

**Spectrum A** Heavy and decoupled new quark scenario. The new quarks $Q_H$ are chosen to be heavier than $Z'$. Specifically we take $m_{Q_H} = m_{Z'} + 1$ TeV, and thus channels of the new quarks will not be considered in the $Z'$-resonance searches. On the other hand, the new leptons $L^H_H$ are assumed to be lighter than $Z'$ with $m_{L^H_H} \approx 2 m_D$ in which $m_D$ is the dark matter mass. Hence $L^H_H$ can be pair produced by $Z'$ on-shell decays. In order to well separate the spectrum, we fix the mass ratio between DM and the $SU(2)_H$ gauge bosons: $m_{Z'} \simeq m_{W^{(p.m)}} = 5 m_D$.

**Spectrum B** Light new quark scenario. For completeness, we also study a scenario with lighter new quarks where the new heavy quarks and leptons are degenerate: $m_{Q_H} = m_{L^H_H} = 2 m_D$, while the same DM-$Z'$($W^{(p.m)}$) mass ratio $m_{Z'} \simeq m_{W^{(p.m)}} = 5 m_D$ as in Spectrum A is assumed.

To achieve $m_{Z'} \simeq m_{W'}$, one needs $v_\Phi \gtrsim 3 v_\Delta \gg v$ based on Eq. (3). Note that this setup is different from the previous work [14], where $v_\Delta \gtrsim v_\Phi \gg v$ was assumed. Furthermore, for simplicity decays of the heavy gauge bosons into scalar Higgs pairs are presumed to be either kinematically forbidden or negligible. It is justified since all of the new scalars except for DM can be heavier than $W'$ and $Z'$ as displayed in the last table in Appendix B. Moreover, the coupling between the longitudinal components of $W'$ and $Z'$ and the DM can in principle be made small by varying the parameters in the scalar potential. In this way, the transverse components (whose coupling to DM is simply $g_H$) govern decays of $W'$ and $Z'$ into DM particles but this contribution to the decays is subleading compared to those of the heavy fermions in the final states, given the larger number of the new fermions in the model.

In both scenarios, the new heavy fermions are kinematically allowed to be produced by either $Z'$ or $W^{(p.m)}$ decays. As a result, we propose searches for the new fermions as follows.\(^2\)

- For Spectrum A, the heavy charged leptons can be produced via $pp \to Z' \to L^H_H L^H_H$ and $pp \to W^{(p.m)} W^{(p.m)} \to L^H_H L^H_H L^H_H$, and the corresponding final states will be (1) $2 l + \not{E}_T$, (2) $2 \tau + \not{E}_T$, (3) $4 l + \not{E}_T$, (4) $2 l + 2 \tau + \not{E}_T$, and (5) $4 \tau + \not{E}_T$.

- For Spectrum B, the new quark pairs can also be on-shell produced through $pp \to Z' \to Q^H_H Q^H_H$, and thus the final states (1) $2 j + \not{E}_T$, (2) $2 b + \not{E}_T$, and (3) $2 t + \not{E}_T$ will be considered. These processes are relevant to the dijet plus missing transverse energy searches for $Z'$. Needless to say, the continuum contributions from QCD to the new quark pair production should be taken into account.

In Tables 2 and 3, we list the branching ratios for the $Z'$ and $W^{(p.m)}$ decays, respectively, in the two scenarios.\(^3\) The $Q^H_H Q^H_H$ final state in the $Z'$ decay is kinematically allowed in Spectrum B, resulting in smaller partial decay widths into the SM $Q^H_H$ and $L^+ L^-$ final states compared to Spectrum A. On the other hand, since $W^{(p.m)}$ do not decay into SM fermion pairs, the opening of $Q^H_H Q^H_H$ final state in Spectrum B affects only the other exotic leptonic channels. These exotic decays can be phenomenologically interesting as we will see in the next section.

Note that $Z'$ and $W^{(p.m)}$ can also decay into scalars, $H$, $\Phi$, $\Delta_H$, which are charged under $SU(2)_H$. The branching fractions, however, depend on the scalar mixing parameters in the scalar potential [14] which can make the analysis

\(^2\) The symbol $l$ refers to the first and second generation charged leptons, $e$ and $\mu$, as well as their antiparticles, while $\tau$ denotes the third generation ones. Similarly, $j$ refers to a light quark/antiquark jet of the first and second generations, and $b$ and $t$ are the bottom/anti-bottom and top/anti-top jets, respectively.

\(^3\) In fact, the branching ratio for each decay mode is insensitive to $m_{Z'}$ and $m_{W^{(p.m)}}$ in the region of interest from 1.5 to 3 TeV.
In G2HDM, \( Z' \) dilepton and dijet searches at the LHC, the heavier must be produced pair-wise in the light of the partial decay widths are simply fixed by the \( SU(2)_L \) symmetry in this work, we neglect scalar final states and instead rather convoluted. As mentioned earlier, to simplify the analysis in this work, we neglect scalar final states and instead focus on the fermion channels at which the corresponding partial decay widths are simply fixed by the \( SU(2)_H \) gauge coupling as well as the new heavy fermion masses.

4 \( Z' \) searches at the LHC

In this section, we first present the \( Z' \) constraints, derived from the ATLAS and CMS dijet and dilepton searches based on the 13 TeV data. Then we propose potential \( Z' \) signatures from exotic decay searches which have smaller cross sections than direct \( Z' \) searches but can be explored at the 14 TeV HL-LHC. In Sect. 5, we will investigate the \( W'^{l(p),m} \) searches at a future proton–proton 100 TeV collider. As mentioned before, unlike \( Z' \), which can be singly created and probed directly by dilepton and dijet searches at the LHC, the heavier \( W'^{l(p),m} \) must be produced pair-wise in the light of the \( SU(2)_H \) gauge symmetry and therefore are less constrained.

4.1 Constraints on \( Z' \) from current dilepton and dijet searches

In G2HDM, \( Z' \) is always lighter than \( W' \) and can be directly probed by resonance searches as mentioned above. Due to the null results of the direct searches, very stringent limits are imposed on any model of \( Z' \) that directly couples to the SM fermions. For instance, the sequential SM with \( Z' \) having the same couplings to SM fermions as the SM Z gauge boson is constrained to be heavier than 4 TeV [27,28].

Recently, the ATLAS and CMS collaborations have reported their updated results of \( Z' \) resonance searches for channels of dilepton [27,28], dijet [25,29], \( b \)-quark pair [30], \( t \)-quark pair [31], and other bosonic final states [32–34] at 13 TeV. In the light of the irreducible QCD background at the LHC, the dilepton channel is the cleanest one to reconstruct the invariant mass of the final state particles and yields the most stringent constraints. In this work, we consider two major type of constraints: dilepton and dijet channels. We calculate the cross sections of \( pp \rightarrow Z' \rightarrow l^+l^-/jj \) with the help of \( \text{Madgraph5} \ [51] \) and compare them with the latest constraints from the LHC.

In Fig. 1, we present the exclusion regions of \( g_H \) as a function of \( m_{Z'} \). The solid lines correspond to Spectrum A and the dashed lines denote Spectrum B. The major discrepancies between the two scenarios are the branching ratios of the \( Z' \) decay into SM quarks and leptons, as shown in Table 2. Compared with the previous constraints [14] obtained from the 8 TeV data, the improvement is about a factor of 2 in the region of \( 1.5 < m_{Z'} < 2.25 \) TeV. In addition, thanks to the higher center-of-mass energy \( \sqrt{s} (8 \rightarrow 13 \) TeV), the bounds for \( m_{Z'} > 2.25 \) TeV are significantly improved and become stronger than the LEP limits based on the \( \sigma(e^+e^- \rightarrow l^+l^-) \) measurements [14].

We note that the constraints on the \( Z' \) mass in G2HDM is less stringent than the \( Z' \) in LRSM or LRTHM where a discrete symmetry is imposed to equate the new gauge coupling to the SM \( SU(2)_L \) one. The price to pay for G2HDM is, of course, a smaller \( g_H \).

4.2 \( Z' \) exotic decays into heavy fermions

We now move on to the \( Z' \) exotic decays which can shed light on the existence of exotic fermions in G2HDM. As noted before, the scalar decay channels of \( Z' \) depend on details of the complicated scalar potential and hence are ignored in this work. On the other hand, the heavy fermion channels, which are governed by \( g_H \) and the heavy fermion masses only, can easily be addressed.

Thinking forwardly and optimistically, one can envisage that a \( Z' \) will be discovered by the direct searches of dilepton and dijet channels in the foreseeable future at HL-LHC. If so, the heavy fermions in G2HDM can also be probed via \( Z' \) on-shell decays if kinematically allowed. In order to perform a more general study for this purpose, we will temporarily relax the mass relations among the heavy fermions, \( Z' \), and DM for both Spectrum A and Spectrum B mentioned in Sect. 3. To be specific, in this section and only in this section, we will relax the fixed mass relation in Spectrum A to \( 2m_{L_H^0} < m_{Z'} < 2m_{Q_H^0} \), and for Spectrum B we will assume \( 2m_{(L_H^0, Q_H^0)} < m_{Z'} \) instead. Besides, as long as the mass differences between the heavy fermions and DM are large enough, the actual value of \( m_{DM} \) will not have a significant impact on the analysis.

![Fig. 1](image-url)
Thus we will choose a nominal value of \( m_{\text{DM}} = 50 \) GeV in the following analysis. These two modified spectra will be referred to as Spectrum \( \Lambda' \) and Spectrum \( \Lambda'' \) in what follows.

Owing to the \( SU(2)_L \) symmetry, final states of the exotic decay modes are quite similar to those used to search for supersymmetric (SUSY) particles with R-parity conservation in the context of the Minimal Supersymmetric Standard Model (MSSM). For example, for the slepton (\( l^\pm \)) searches at the LHC the major process is \( 2l + E_T \) channel, namely

\[
pp \rightarrow \gamma/Z \rightarrow l^+ l^- \rightarrow 2l + E_T, \tag{9}
\]

Similarly, in G2HDM, decays of \( Z' \) into a pair of exotic fermions can also lead to the same final states:

\[
pp \rightarrow Z' \rightarrow l^H l^H \rightarrow 2l + E_T. \tag{10}
\]

These two processes with the same final states exhibit analogous event topology, allowing us to apply the same kinematic cuts.\(^4\) We calculate the cross sections for the analogous event topology, allowing us to apply the same kinematic cuts.

The bounds on the heavy fermion masses can be mitigated in a scenario of the compressed mass spectrum: \( m_{(l^H, \mu^H)} \gtrsim m_{\text{DM}} \). In this case mono-X (\( X = \gamma, g, W, Z, \cdots \) + \( E_T \)) in particular the monojet + \( E_T \) signal, can be used to search for DM as in the MSSM with the compressed mass spectrum. This scenario, however, will not be considered here as the mass difference \( m_{(l^H, \mu^H)} - m_{\text{DM}} \) is taken to be large.

We now present the constraints on the \( Z' \) exotic decays. With the modified spectra, we will be able to obtain contours of the production cross sections on the \( m_{Z'} - m_{l^H} \) plane and compare with the LHC limits on the SUSY particle searches.

- Spectrum \( \Lambda' \): \( 2 m_{l^H} < m_{Z'} < 2 m_{\mu^H} \) and \( m_{\text{DM}} = 50 \) GeV.

We concentrate on the following two channels:

\[
pp \rightarrow Z' \rightarrow l^H l^H \rightarrow 2l + E_T, \tag{11}
\]

\[
pp \rightarrow Z' \rightarrow \tau^H \tau^H \rightarrow 2\tau + E_T, \tag{12}
\]

where \( l^H = (e^H, \mu^H) \), and \( l = (e, \mu) \). In Fig. 2, the contour plots for the cross sections of the processes in (11) and (12) are shown on the \( m_{Z'} - m_{l^H} \) (left panel) and \( m_{Z'} - m_{\tau^H} \) (right panel) planes. Since the cross section is proportional to \( g_H^2 \) for on-shell heavy fermions,\(^5\) the results are shown in terms of \( \sigma/g_H^2 \) to factor out the \( g_H \) dependence. For a specific value of \( g_H \), one can simply rescale the contours by \( g_H^2 \) whose limits for a given value of \( m_{Z'} \) have been presented in Fig. 1. The black, blue, and red contours correspond to \( \sigma/g_H^2 = 0.1, 0.05, \) and 0.01 pico-barn (pb) respectively, assuming \( \sqrt{s} = 14 \) TeV.

We employ the recent results of ATLAS SUSY searches for neutralinos and charginos based on the \( 2l + E_T \) and \( 2\tau + E_T \) channels to constrain the \( Z' \) exotic decays in G2HDM. The resulting bounds should be regarded as estimated constraints, as the signal regions and efficiency may have some differences between MSSM and G2HDM. For the left panel of Fig. 2 (\( 2l + E_T \) channel), we use the signal region \( SR2l-A \), which refers to a set of event selections listed in Table 1 of Ref. [57]. It gives rise to the constraint \( \langle \sigma \rangle_{\text{obs}} \leq 1.89 \) fb at 13 TeV. Assuming that the factor of signal efficiency \( e \) is of \( O(1) \) at 14 TeV,\(^6\) we can infer limits on \( g_H \) at the 14 TeV LHC in the following way. For instance, to satisfy the \( SR2l-A \) bound \( \sigma < 1.89 \) fb, along the black, blue and red contours in the left panel of Fig. 2, the corresponding \( g_H \) is required to be smaller than 0.137, 0.194, and 0.435, respectively.

Likewise, for the \( 2\tau + E_T \) channel on the right panel of Fig. 2, we utilize the \( SRC1c1 \) signal region in Ref. [58]. It yields \( \langle \sigma \rangle_{\text{obs}} \leq 0.33 \) fb at 13 TeV, which demands \( g_H \) to be less than 0.057, 0.081, and 0.182 for the black, blue, and red contours, respectively.

Two comments are in order here, regarding the discrepancies between collider searches discussed here for MSSM and G2HDM.

1. The signals of \( 2l + E_T \) and \( 2\tau + E_T \) in Spectrum \( \Lambda' \) mainly come from Drell–Yan processes for both G2HDM and MSSM. The major difference between the two models is the distribution of the invariant mass of the final charged leptons. In G2HDM, the invariant mass distributions have a cut-off at \( m_{Z'} \), i.e., \( m_{l^+l^-}, m_{\tau^+\tau^-} < m_{Z'} \), while \( m_{l^+l^-} \) and \( m_{\tau^+\tau^-} \) are more evenly distributed in MSSM. This is because the underlying Drell–Yan processes are mostly mediated by the on-shell \( Z' \) in G2HDM, but by the off-shell SM \( \gamma \) and \( Z \) for MSSM, as indicated in Eqs. (9) and (10).

2. If the on-shell \( Z' \) is highly boosted and the mass splitting between \( Z' \) and the new leptons is large, one will have two collinear outgoing new leptons which result

\(^4\) The process in Eq. (10) is the major contribution to the \( 2l + E_T \) channel in G2HDM, although there are also the processes \( pp \rightarrow \gamma/Z \rightarrow l^H l^H \rightarrow 2l + E_T \), similar to those in Eq. (9).

\(^5\) For most of the regions of interest, the extra heavy fermions from \( Z' \) decays are on-shell.

\(^6\) If the magnitudes of the cross sections at 14 TeV are just slightly larger than those at 13 TeV, the constraints we present here will be more stringent than the 13 TeV ones, since the detection efficiency of order 1 has been assumed.
in two collinear SM leptons. In contrast, MSSM will not exhibit such a collinear behavior due to lack of $Z'$, and so one can distinguish G2HDM from MSSM via the event topology of dilepton plus missing transverse energy signals.

- Spectrum B': $2m_{(L,\phi)} < m_{Z'}$ and $m_{DM} = 50$ GeV.

For the new quarks, they can always be pair produced dominantly by strong processes, like $q\bar{q}, gg \rightarrow Q^H Q^H$ via $s$-channel gluon exchange or $t$-channel heavy exotic quark exchange. The cross sections for the strong processes

$$ pp \rightarrow j^H j^H \rightarrow 2j + E_T^*, \quad (13) $$

$$ pp \rightarrow b^H b^H \rightarrow 2b + E_T^*, \quad (14) $$

$$ pp \rightarrow t^H t^H \rightarrow 2t + E_T^*, \quad (15) $$

where $j^H = (u^H, d^H, c^H, s^H)$ and $j = (u, d, c, s)$ are computed. On the other hand, processes involving intermediate squarks can lead to exactly the same final states, $2j + E_T^*, 2b + E_T^*$ and $2t + E_T^*$. Consequently, the LHC results of SUSY squark searches [59–61] can be directly used for our case.

First, we choose the signal region $2j - 1200$ [59] for the $2j + E_T^*$ channel, which yields $\langle \epsilon \sigma \rangle_{obs}^{95} \lesssim 3.6$ fb with $\epsilon \sim 35\%$. Second, for the $2b + E_T^*$ channel, the signal region SRA250 [60] is chosen. The resulting limit is $\langle \epsilon A \sigma \rangle_{obs}^{95} \lesssim 3.42$ fb with $\epsilon A \sim 10\%$. Third, for the $2t + E_T^*$ channel, the signal region SRA-T0 [61] is involved and the corresponding limit is $\langle \epsilon A \sigma \rangle_{obs}^{95} \lesssim 0.40$ fb with $\epsilon A \sim 9\%$. In the left column of Fig. 3, the red lines represent these cross sections, dominated by the strong interactions, at $\sqrt{s} = 13$ TeV as functions of $m_Q$, while the gray shaded regions are excluded by the recent ATLAS 13 TeV results. The cross section bounds can be translated into the new quark mass limits. Clearly, from the left column of Fig. 3, we have $m_{j^H} \gtrsim 1.4$ TeV, $m_{b^H} \gtrsim 1$ TeV, and $m_{t^H} \gtrsim 1.3$ TeV. Note that these mass bounds are independent of the $SU(2)_H$ coupling $g_H$, since the dominant cross sections here arise from pure QCD interactions.

On the other hand, if $m_{Z'} > 2m_Q$, three subdominant but nevertheless important processes have to be included:

$$ pp \rightarrow Z' \rightarrow j^H j^H \rightarrow 2j + E_T^*, \quad (16) $$

$$ pp \rightarrow Z' \rightarrow b^H b^H \rightarrow 2b + E_T^*, \quad (17) $$

$$ pp \rightarrow Z' \rightarrow t^H t^H \rightarrow 2t + E_T^*. \quad (18) $$

We display the corresponding cross section contours, similar to Fig. 2 in Spectrum A', on the $m_{Z'} - m_{j^H}, m_{Z'} - m_{b^H}$, and $m_{Z'} - m_{t^H}$ planes, respectively, in the right column of Fig. 3. The previous bounds on the new quark masses translated from the SUSY searches are also shown by the dashed lines. Because of the stringent mass limits which push the new quark mass scale beyond TeV, the production cross sections of the new quarks via the $Z'$ exotic decays are kinematically suppressed and hence constrained to be small: $\sigma / g_H^2 \lesssim 0.01$ pb as can be seen from the right column of Fig. 3.

5 Future $W'$ searches

In the event that $Z'$ is discovered at HL-LHC via dijet or dilepton searches, one can ask whether it comes from an additional $SU(2)$ gauge symmetry or simply from an extra $U(1)'$. In this section, we discuss how to look for the electrically neutral $W'(p,m)$ whose existence will help to pin down the $SU(2)_H$ as a potential underlying symmetry in nature.
5.1 $W'$ in different $SU(2)$ models

Before embarking on our detailed analysis, we should point out that there exist, of course, many other well-motivated models with neutral $W'$ gauge bosons in addition to $Z'$, such as THM [23, 24], 3-3-1 models [62, 63], etc. Certainly, any non-abelian gauge group commutes with the SM $SU(2)_L \times U(1)_Y$ gauge groups, naturally accommodates neutral $W'$. Here we will not manage to compare the $W'(p, m)$ of G2HDM with all models featuring neutral $W'$. Instead, we focus on collider signals of $W'(p, m)$ in our model and contrast them with LHT with T-parity—a representative composite Higgs model which has neutral $Z'$ and charged $W'$ [20–22].
Table 4 Comparison of quantum numbers of the heavy SU(2)_{L} singlet fermion fields in G2HDM and LHT

|                | G2HDM | LHT |
|----------------|-------|-----|
|                | U_{R} | D_{R} | u_{R}^{H} | d_{R}^{H} | N_{R} | E_{R} | \nu_{L}^{H} | e_{L}^{H} | q_{H} | t_{H} | d_{H} | l_{H} | e_{H} |
| SU(3)_{C} | 3 | 3 | 3 | 3 | 1 | 1 | 1 | 3 | 3 | 3 | 1 | 1 |
| SU(2)_{H} | 2 | 2 | 1 | 1 | 2 | 2 | 1 | / | / | / | / | / | /
| SU(2)_{T} | / | / | / | / | / | / | / | / | / | / | / | / | /
| \tau_{T} | / | / | / | / | / | / | / | / | / | / | / | / | /

In the absence of the symmetries in the models, we put a slash in the cells. \tau_{T} is the T-parity in LHT.

Both Z’ and W’ in LHT can only be produced in pairs due to T-parity and have the same signals, just like W^{(p,m)} in G2HDM. In other words, LHT is chosen as an illustrative example to underscore differences in the context of collider searches. Since W^{(p,m)} in G2HDM is always heavier than Z’, it might not be easy to produce a pair of W^{(p,m)} (or even Z’) at the LHC, we will focus on the future 100 TeV proton–proton collider. To identify SU(2)_{H} unambiguously, the discovery of new heavy fermions Q^{H} and L^{H} as well as scalars like \Delta_{H} and \Phi_{H} will also be necessary on top of W^{(p,m)} and Z’.

We note that LRSM [18,19] has the right-handed charged W_{R}^{\mp}. It can be singly produced and directly probed by dijet resonance [64,65] or same-sign dilepton plus two jets (l^{\pm}l^{\pm}jj) searches [66], depending on the right-handed neutrino mass, whereas W^{(p,m)} in G2HDM must be pair produced. Due to quite different properties between W^{(p,m)} and W_{R}^{\mp} and the stringent bound on Z_{R}: m_{Z_{R}} > 3.2 TeV [35], LRSM will not be considered here.

The LHT model discussed here is based on the coset manifold SU(5)/SO(5), which can be realized as a nonlinear sigma model [20–22]. Two different SU(2) \times U(1) subgroups of SU(5) are gauged and are broken down to the SM electroweak gauge group SU(2)_{L} \times U(1)_{Y}, at a scale \Lambda_{T}, which is higher than but not too far away from the electroweak scale so as to provide a possible solution to the fine-tuning problem. In the LHT model, all particles are divided into two classes based on the T-parity (denoted by \tau_{T} hereafter), which corresponds to the symmetry under the exchange of the two SU(2) \times U(1) subgroups. As a result, combinations of different fields of the two subgroups can be formed as having eigenvalue +1 or − 1 of \tau_{T}. The lightest T-odd particle is \tilde{A}_{H}, a spin 1 particle, which is ensured to be stable and hence can be a DM candidate. Novel collider signatures like monojet and dijet plus missing transverse energy of \tilde{A}_{H} in LHT was studied in [67]. All of the exotic particles have masses proportional to \Lambda_{T}, since the masses are induced from the collective symmetry breaking at the scale \Lambda_{T}. Furthermore, the exotic fermions couple to T-odd combinations of the gauge bosons of (SU(2) \times U(1))^{2}. Three of the combinations comprise a non-abelian group SU(2)_{T}, which is broken at the scale \Lambda_{T}. In the end, the exotic T-odd SU(2)_{T} gauge bosons should couple to one T-even and one T-odd particle so as to conserve T-parity. We will use Z_{H} and W_{H}^{\mp} to denote the SU(2)_{T} gauge bosons in the LHT, as opposed to Z’ and W^{(p,m)} in G2HDM. The quantum numbers of additional SU(2)_{L} singlet fermions in the G2HDM and LHT are summarized in Table 4. Note that the superscript \textit{H} is specifically used to indicate the G2HDM exotic fermions, while the subscript \textit{H} denotes the LHT new fermions.

5.2 Two search channels: 2l + \cancel{E_{T}} and 4l + \cancel{E_{T}}

In G2HDM, the W^{(p,m)} boson pair is produced via the Z’ and Q^{H} exchange, while the pair productions of W_{H}^{\pm}W_{H}^{\mp} and Z_{H}Z_{H} are through the γ, Z, and q_{H} exchange in LHT. We will focus on leptonic decay channels for these gauge boson pairs because of the low QCD background as in the Z’ resonance searches. The final states of two and four leptons plus the missing transverse energy, 2l + \cancel{E_{T}} and 4l + \cancel{E_{T}}, respectively, will be investigated.

Take the W^{(p,m)} pair in G2HDM as an example. The 2l + \cancel{E_{T}} channel comes from the prompt decay of one of the two gauge bosons into one heavy charged lepton plus one SM lepton, while the other boson into one heavy neutrino plus one light neutrino. Each of the two resulting heavy fermions then decays into the DM particle \tilde{H}^{0}_{\tau} plus the corresponding light SM fermion through the Yukawa couplings from (2). The neutrinos and DM particles in the final state will escape from the detector and become manifest as \cancel{E_{T}}. In Table 5, we summarize the decay chains of the gauge boson pairs into 2l + \cancel{E_{T}} and 4l + \cancel{E_{T}}. In the last column labeled by signal, the particles inside the curly brackets become manifest as \cancel{E_{T}}.

5.3 The quantitative study: cross sections

In Fig. 4, we show the cross sections as functions of the corresponding gauge boson mass for the channels 2l + \cancel{E_{T}} and 4l + \cancel{E_{T}} (l = e, \mu) with \sqrt{s} = 100 TeV in both G2HDM (left panel) and LHT (right panel). The solid (dashed) line corresponds to Spectrum A (Spectrum B), while the red (blue) line refers to the channel 2l + \cancel{E_{T}} (4l + \cancel{E_{T}}). Here we apply the same Spectrum A and Spectrum B for the gauge bosons, heavy exotic fermions, and DM in G2HDM to the corresponding particles in LHT.
Table 5 List of the production and leptonic decay channels for the exotic gauge bosons in G2HDM and LHT

| Model  | Production | Prompt decay | Final state | Signal |
|--------|------------|--------------|-------------|--------|
| G2HDM  | pp → W′pW′m | (7H) (7H) + c.c. | (7H) (7H) + c.c. | l′l′ + {7H} |
| LHT    | pp → W_HW_H | (7_H) (7_H) + c.c. | (7_H) (7_H) + c.c. | l′l′ + {7H} |
| LHT    | pp → ZZ_HH | (7_H) (7_H) + c.c. | (7_H) (7_H) + c.c. | l′l′ + {7H} |

For G2HDM, the upper bound from the Z' resonance searches on the gauge coupling g_H from Fig. 1 is used. In other words, the region above the line in each case is excluded. That is the reason why the cross sections, which scale as g_H^4, increase when m_W (and also m_z') become larger, since the bound on g_H becomes less stringent. By contrast, in LHT the gauge coupling is set equal to the SM electroweak coupling and thus the cross sections decrease as the gauge boson mass increases.

We should point out that in G2HDM the process pp → Z' → ZZ_H is actually the dominant contribution to the final state 2l + E_T. If Z’ is discovered in the resonance searches, as assumed here, one should be able to infer the precise values of g_H and m_z'. Therefore, the dominant Z' contribution can be subtracted from the data so that one can study the contributions from pp → W′pW′m alone. Alternatively, as we shall see later one can also resort to the 4l + E_T final state for W'(p,m) searches. It is a relatively clean channel and is free from pp → Z' pollution. The corresponding cross section is only three times smaller than that of the 2l + E_T channel. Finally, the Z’ pair production pp → Z’Z’ will also produce the 2l + E_T and 4l + E_T signals. The contributions, however, are at least two orders of magnitude smaller than those from pp → W′pW′m, and therefore will be neglected in our analysis.

In LHT, the cross section of pp → W_HW_H is about one order of magnitude larger than pp → ZZ_H production at √s = 100 TeV. That is because W_HW_H is produced dominantly by the s-channel γ and Z exchange, which is larger than the main contribution from the t-channel q_H exchange to the ZZ_H production. Consequently, the cross section for 2l + E_T, mostly from the W_HW_H channel, is almost one order of magnitude larger than that of 4l + E_T, which arises only from ZZ_H channel. As seen from Fig. 4, however, the cross sections for both 2l + E_T and 4l + E_T are of the same order in G2HDM. On the other hand, the cross sections for both of these channels in LHT are roughly 1–2 orders of magnitude larger than those in G2HDM, depending on the gauge boson mass. Thus, one can in general distinguish the two models just by measuring the total cross sections of the two channels.
5.4 The qualitative study: the kinematical distributions

In this section, we will further investigate the difference between G2HDM and LHT gauge boson decays in terms of three different normalized kinematical distributions. In principle, one should be able to distinguish the electrically charged \( W^\pm \) from the neutral \( W'_0 \) by the total charge of the corresponding decay products once they are produced singly. Both \( W^{(p,m)} \) and \( W'_\pm \), however, have to be pair produced because of the \( SU(2)_H \) and \( SU(2)_T \) symmetry, respectively, which lead to the same total charge of the final states. As a consequence, the kinematical distributions of \( W^{(p,m)}_0 \) and \( W'_\pm \) decays are not only interesting but also important to study for further information, even though the production cross sections, as shown in previous Section, are in general much larger in LHT than in G2HDM.

Let \( X \) denote \( W^{(p,m)}_0 \), \( W'_\pm \), or \( Z_H \), notwithstanding the same symbol has been used for the \( U(1)_X \) gauge boson which has been assumed to be very heavy and decoupled. In four benchmark points \( m_X = 0.5, 1.5, 3.0, \) and \( 4.0 \) TeV, we will show the normalized kinematical distributions of the spatial separation \( \Delta R_{e^+ e^-} \) (Fig. 5) and invariant mass \( M_{e^+ e^-} \) (Fig. 6) of the electron pair in the \( 2l + E_T \) channel, and the invariant mass \( M_{e^+ e^- \mu^+ \mu^-} \) (Fig. 7) of four leptons in \( 4l + E_T \) channel.\(^7\) The muon has the same distributions of \( \Delta R_{\mu^+ \mu^-} \) and \( M_{\mu^+ \mu^-} \) as the electron and will not be discussed separately. For comparison, the benchmark point \( m_X = 0.5 \) TeV is also included because its distribution shape is clearly distinguishable from the SM background. The corresponding coupling \( g_H \) for \( m_X = 0.5 \) TeV shall be appropriately small to avoid the current LHC limits as shown in Fig 1. The normalized kinematical distributions, nonetheless, do not depend on the values of \( g_H \) that we shall keep in mind here and hereafter. In addition, the distributions do not change significantly between the two spectra and we simply choose Spectrum A. The leading order irreducible SM background for each kinematical distribution is also presented for comparison. Further discussions of these three distributions are as follows.

\(^7\) The spatial separation between particles is defined as \( \Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} \), where \( \Delta \eta \) and \( \Delta \phi \) are the differences in pseudorapidity and the azimuthal angle, respectively. On the other hand, the invariant mass squared between particles is defined as \( M^2 = (\Sigma_i p_i)^2 \), where \( p_i \) is the four-momenta of particle \( i \).
Fig. 6 Comparison of the normalized distributions of the invariant mass $M_{e^+e^-}$ in G2HDM (blue), LHT (red), and SM (black) computed at $\sqrt{s} = 100$ TeV with $m_X = 0.5$ TeV (top-left), 1.5 TeV (top-right), 3.0 TeV (bottom-left), and 4.0 TeV (bottom-right).

First, the spatial separation $\Delta R_{e^+e^-}$ - the distribution for $W^{\pm}(p,m)$ is distinct from that of $W^\pm Z$. As shown in Table 5, the final lepton pair $l^+l^-$ is coming from different decay patterns of the gauge bosons $W^\pm W^\mp$, $W^+H_H^-$, or $Z_H Z_H$ in the two models. In G2HDM, both $l^+$ and $l^-$ are coming from either $W^+$ or $W^-$, while in LHT there are two possible routes—(1) $l^+$ from $W^+_H$ and $l^-$ from $W^-_H$, and (2) both $l^+$ and $l^-$ from either one of the $Z_H$ in the $Z_H Z_H$ pair. Overall, since $W^+_H W^-_H$ pair production has a much larger cross section than $Z_H Z_H$, for the two leptons in the final state, $l^+$ mainly comes from $W^+_H$ and $l^-$ from $W^-_H$; it leads to a larger $\Delta R_{e^+e^-}$ in LHT than in G2HDM. Note that the distinction between the two models also depends on to what measure the gauge boson $X$ is boosted. If $X$ is highly boosted (e.g. $m_X = 0.5$ TeV in Fig. 5), the distinction between G2HDM and LHT becomes more visible. For the SM case, the main contributions result from the $W^+ W^-$ pair, each of which decays into a charged lepton and a neutrino, resulting in a large separation $\Delta R_{e^+e^-}$ similar to the LHT case as is clearly reflected in Fig. 5.

Second, for the same reason as in the $\Delta R_{e^+e^-}$ distribution, the invariant mass of the lepton pair $M_{e^+e^-}$ should be smaller than $m_{W^{\pm}}$ in G2HDM (or $m_{Z_H}$ in LHT). From the position of the $M_{e^+e^-}$ cut-off, one can roughly infer the mass $m_{W^{\pm}(p,m)}$. On the other hand, the invariant mass spectrum is distributed more evenly in the $X = W_H^+$ case. For the SM, $M_{e^+e^-}$ is centered around $m_Z$ as well as the low-mass region due to $W^+ W^-$ pair, off-shell $\gamma/Z$ and other non-resonance contributions. The SM contribution is, of course, independent of $m_X$ and is shown only in the top-left panel of Fig. 6 to highlight the difference from the new physics. Therefore, one can simply impose appropriate cuts on $M_{e^+e^-}$ to reduce the SM background and extract either G2HDM or LHT signals for different $m_X$ at $\sqrt{s} = 100$ TeV. From Fig. 6, one can clearly distinguish among the G2HDM, LHT, and SM by the $M_{e^+e^-}$ distributions.

Last but not least, the cross section of the $4l + E_T$ channel is about three times smaller than those of $2l + E_T$ for $W^{\pm}(p,m)$ searches in G2HDM, as can be seen in the left panel of Fig. 4. Due to the facts that only $W^{\pm}(p,m)$ in G2HDM and $Z_H$ in LHT contribute to this channel and both of them are neutral, similar distributions of $M_{e^+e^-} \mu^+\mu^-$ in G2HDM and LHT, as exhibited in Fig. 7, are expected. However, their distributions are clearly distinguishable from those of the SM, which arise from on-shell $Z$ decays and consequently peak toward low-energy regions. Thus, the final state of four leptons plus missing transverse energy can be used to detect physics beyond the SM. However, to distinguish G2HDM...
Fig. 7 Comparison of the normalized distributions of the invariant mass $M_{e^{+}e^{-}\mu^{+}\mu^{-}}$ in G2HDM (blue), LHT (red), and SM (black) computed at $\sqrt{s} = 100$ TeV with $m_{X} = 0.5$ TeV (top-left), 1.5 TeV (top-right), 3.0 TeV (bottom-left), and 4.0 TeV (bottom-right).

from LHT is not easy using the $4l + E_{T}$ channel unless $M_{X}$ is $\lesssim 0.5$ TeV, in which case a much smaller $g_{H}$ is anticipated.

From our studies of the two channels of two/four leptons plus missing transverse energy, one can conclude that in addition to the production cross sections, the kinematical distributions are also indispensable to discriminate the two models, G2HDM and LHT.

6 Summary and outlook

One of the most interesting features in G2HDM [14], where the two Higgs doublets, $H_{1}$ and $H_{2}$, are paired up to form a doublet of a new local $SU(2)_{H}$ gauge group, is the occurrence of three electrically neutral gauge bosons, $Z'$ and $W'^{\pm}(p,m)$. The $SU(2)_{H}$ is broken by the vevs of the triplet $\Delta_{H}$ and a doublet $\Phi_{H}$ from which a vev for the SM doublet $H_{1}$ is induced as well while $H_{2}$ is inert. As a result, all weak gauge bosons other than the photon got their masses. The extra heavy fermions $Q^{H}$, $L^{H}$ and $\nu^{H}$, required by the anomaly cancellation with the SM fermions, provide gauge invariant Yukawa couplings in Eqs. (1) and (2) with the scalar doublets $H_{1}$, $H_{2}$, and $\Phi_{H}$ to give masses to all fermions. While $Z'$ can decay into a pair of new heavy fermions, $W'^{\pm}(p,m)$ can only decay into a new heavy fermion and a SM fermion. The heavy fermion can decay into a SM fermion plus missing energy carried by the DM candidate $H_{0}^{2}$, whose stability is protected by an emergent $Z_{2}$ symmetry.

In this work, we studied collider signals of $Z'$ and $W'^{\pm}(p,m)$ which can help us to pinpoint G2HDM. We derived constraints on $Z'$ from the LHC 13 TeV data, followed by investigations of the future 14 TeV LH-LHC and 100 TeV proton–proton collider searches for $Z'$ and $W'^{\pm}(p,m)$. The main difference between $Z'$ and $W'^{\pm}(p,m)$ is that $Z'$ can be singly produced and decay into SM fermions, while $W'$ has to be pair produced in the light of the $SU(2)_{H}$ gauge symmetry. It leads to stringent bounds on the $SU(2)_{H}$ coupling $g_{H}$ and the mass $m_{Z'}$ from the LHC direct searches based on the Drell–Yan type dilepton and dijet final states.

The updated LHC limit shown on the $m_{Z'}-g_{H}$ plane in Fig. 1 is roughly a factor of 2 improvement in the low-mass region $m_{Z'} \lesssim 2.25$ TeV compared to the previous results [14] inferred from the LHC-8 dilepton data. In addition, for the whole region of $m_{Z'}$ of interest, the dilepton constraints on $g_{H}$ now become more stringent than those deduced from LEP and the electroweak precision data. Even the dijet bounds,
which suffer from the QCD background, are also stronger than the LEP bounds for \( m_Z' \lesssim 2.5 \text{ TeV} \).

Moreover, \( Z' \) can also decay into the new fermions which subsequently decay into SM fermions plus the missing transverse energy. We presented the contours of the rescaled cross sections \( \sigma / g_{H}^{2} \) on the plane of the masses of \( Z' \) and new heavy exotic fermions in Figs. 2 and 3 for Spectrum \( \Lambda' \) and Spectrum \( \Lambda'' \), respectively. For Spectrum \( \Lambda' \), we considered final states of two leptons \( (e \bar{e} \text{ and } \mu \bar{\mu}) \) and two \( t \bar{t} \) with missing transverse energy which originate from decays of the exotic heavy leptons. For Spectrum \( \Lambda'' \), two jets, two \( b \)-quarks and two \( t \)-quarks with missing transverse energy coming from the exotic heavy quarks were considered. Using the LHC constraints on \( \langle \sigma \langle \epsilon \sigma \rangle \rangle_{\text{obs}} \) from SUSY searches for the same final states, one can derive limits for the coupling \( g_{H} \) from the contours of \( \sigma / g_{H}^{2} \) on the \( (m_{Z'}, m_{1,H}) \) or \( m_{Z'}-m_{1,H} \) planes (Fig. 2). While the constraints on \( g_{H} \) obtained from exotic decays of \( Z' \) into heavy exotic leptons are comparable with those from the aforementioned dilepton and dijet searches, it appears that there is no severe bound that can be derived on the masses of heavy leptons from the existing data of SUSY searches. On the other hand, Spectrum \( \Lambda'' \), in which the pair production of the exotic quarks is kinematically allowed, has substantial regions being excluded (Fig. 3). The reason is that the dominant contributions to the exotic quark production arise from the QCD processes which are independent of the gauge coupling \( g_{H} \). Thus, stringent limits from LHC on SUSY squark searches can be directly applied to our case, requiring the new quarks to be heavier than 1 TeV or so.

If \( Z' \) can be discovered in the future, the neutral \( W^{\prime}(p,m) \) also need to be found in order to identify G2HDM as the underlying theory. Final states of two and four leptons with missing transverse energy from G2HDM and LHT had been studied in detail to understand different signatures between the neutral \( W^{\prime}(p,m) \) in G2HDM and the gauge bosons, \( Z_{H} \) and \( W \pm \) in LHT. The total cross sections for \( 2l + \not{E}_{T} \) and \( 4l + \not{E}_{T} \) were computed in both models (Fig. 4). In the \( 2l + \not{E}_{T} \) channel, the two final leptons come from the same \( W^{\prime}(p,m) \) in G2HDM, whereas in LHT they come from different \( W^{\pm} \). Therefore, a smaller spatial separation between the final leptons is expected for \( W^{\prime}(p,m) \). Indeed as clearly seen in Fig. 5, the spatial separation of \( e^{+}e^{-} \) in LHT is completely overlapped with the SM one which has larger \( \Delta R_{e^{+}e^{-}} \). Furthermore, by the same reason, the invariant mass of the lepton pair are cut off at the mass of \( W^{\prime}(p,m) \) as opposed to a flatter invariant mass distribution for LHT (Fig. 6). In addition, the \( 4l + \not{E}_{T} \) channel is also investigated. The invariant mass distributions of four charged leptons behave quite differently between the SM and G2HDM (and LHT), whereas LHT and G2HDM exhibit similar distributions (Fig. 7).

We conclude our study by presenting the search strategies of distinguishing G2HDM from LHT in Table 6. For \( Z' \), which can be singly produced, the dilepton final states will be the best search channels. For pair-produced gauge bosons like \( W^{\prime}(p,m) \) in G2HDM, and \( W_{H}^{\pm} \) and \( Z_{H} \) in LHT, apart from the total cross sections, detailed kinematical distributions, such as (i) the spatial separation between the SM lepton pair and (ii) the invariant mass distributions of two and four leptons in the final states, can help us to disentangle these two models.

High luminosity upgrade for the LHC and building a future 100 TeV hadron collider are matters of utmost importance for fully exploring and distinguishing new electroweak scale models, all of which are contrived to address theoretical issues that cannot be answered within the SM.

### Acknowledgements

We thank Van Que Tran and Raymundo Ramos for sharing with us the scan data and useful discussions. TCY would like to thank the hospitality he received at NCTS where ideas of this project were nurtured. CTL would like to thank Dr. Jung Chang for some useful suggestions for the simulation of littlest Higgs models at the beginning of this project. We would like to thank the referee for pointing out a missing term in the scalar potential. The work of TCY is supported by the Ministry of Science and Technology (MoST) of Taiwan under Grant number MOST-104-2112-M-001-001-MY3. WCH is supported by DGF Grant no. PA 803/10-1 and by Danish Council for Independent Research Grant DFF-6108-00623.

### Appendix A: Scalar potential of G2HDM

We here spell out the most general and renormalizable scalar potential invariant under the \( SU(2)_{H} \times U(1)_{X} \) as well as the SM gauge groups, given the particle contents specified in Table 1. There exist two Higgs doublets, \( H_{1} \) and \( H_{2} \) where \( H_{1} \) is identified as the SM Higgs doublet and \( H_{2} \) (with the same hypercharge \( Y = 1/2 \) as \( H_{1} \)) is the additional \( SU(2)_{L} \) scalar doublet. The two Higgs doublets \( H_{1} \) and \( H_{2} \) are embedded into an \( SU(2)_{H} \) doublet \( H = (H_{1} H_{2})^{\dagger} \) with a \( U(1)_{X} \) charge of \( X(H) = 1 \).
In addition to $H$, we introduce the $SU(2)_H$ triplet $\Delta_H$ and doublet $\Phi_H$,

$$\Delta_H = \left( \Delta_3/2, \Delta_p/\sqrt{2} \right), \quad \Phi_H = \left( \Phi_1, \Phi_2 \right).$$ (A1)

with $\Delta_m = (\Delta_p)^* \equiv (\Delta_3)^* = \Delta_3$. Both of them are singlets under the SM gauge groups. The vev of the triplet can induce $SU(2)_L$ symmetry breaking as we shall see below, while that of $\Phi_H$ provides a mass to the new fermions that are necessitated due to the $SU(2)_H$-invariant Yukawa couplings shown in Eqs. (1) and (2). In the following, the $SU(2)_L$ multiplication is implicitly assumed but not denoted otherwise stated.

The scalar potential invariant under $SU(2)_L \times U(1)_Y \times SU(2)_H \times U(1)_X$ reads

$$V(H, \Delta_H, \Phi_H) = V(H) + V(\Phi_H) + V(\Delta_H)$$

$$+ V_{\text{mix}}(H, \Delta_H, \Phi_H),$$ (A2)

with

$$V(H) = \mu_H^2 \left( H^{\alpha i} H_{\alpha i} \right)^2 + \mu_{\Phi H}^2 \left( H^{\alpha i} H_{\alpha i} \right)$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)^2$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)^2$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)^2$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)^2$$

$$+ \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)^2$$

where $\alpha, \beta, \gamma$, and $\delta$ (i, j) refer to the $SU(2)_H$ ($SU(2)_L$) indices; all of them run from one to two and the super-index (subscript) is always attached to $H^\dagger$ ($H$). In light of the equality, $\epsilon_{\alpha\beta\gamma} = \epsilon^{\alpha\beta\gamma}$, one can express $\epsilon_{\alpha\beta\gamma}$ as a linear combination of two independent terms:

$$\left( H^{\alpha i} H_{\alpha i} \right) \left( H^{\beta j} H_{\beta j} \right)$$

and $\left( H^{\alpha i} H_{\alpha i} \right) \left( H^{\beta j} H_{\beta j} \right)$.

An easy way to see that these quartic terms in $H$ and $\Delta_H$ always requires two of the $H^\dagger$ and two of the $H$ to obey the $U(1)_Y$ and $U(1)_X$ symmetry. In this case, one is left with only two options in terms of $H$: $H_{\alpha i} H_{\beta j}$ and $H_{\gamma i} H_{\delta j}$. The first option yields $\left( H^{\alpha i} H_{\alpha i} \right) \left( H^{\beta j} H_{\beta j} \right)$ after gauge index contractions, while the second one is $\left( H^{\alpha i} H_{\alpha i} \right) \left( H^{\beta j} H_{\beta j} \right)$. Any other different $SU(2)$ combinations with either antisymmetric $\epsilon$ (Levi-Civita symbol) or $\delta$ (Kronecker delta) ten-

Note that extra terms $\left( H^\dagger \Delta_H^2 \right)$ and $\left( \Phi_H^\dagger \Delta_H^2 \Phi_H \right)$ are not independent but instead proportional to $H^\dagger H \left( \Delta_H^2 \right)$ and $\left( \Phi_H^\dagger \Phi_H \right) \left( \Delta_H^2 \right)$, respectively, while $\left( \Phi_H^\dagger H \epsilon \right) \left( \Phi_H^\dagger H \epsilon \right)$ can be expressed as $\left( H^\dagger H \right) \left( \Phi_H^\dagger \Phi_H \right) - \left( H^\dagger \Phi_H \right) \left( \Phi_H^\dagger H \right)$.

We should point out that the $\lambda_H^\dagger$ term in Eq. (A3) and the $\lambda_H^\dagger H$ term in Eq. (A4) were not included in the original work [14]. Moreover, all dimensionful mass parameters of
the cubic couplings and dimensionless quartic couplings are necessarily real because every term in the mixed potential \( V_{\text{mix}}(H, \Delta H, \Phi_H) \) in (A7) is Hermitian.

The resulting coefficients of the quadratic terms for \( H_1 \) and \( H_2 \) after spontaneous symmetry breaking of \( SU(2)_H \) induced by \( \langle \Delta_3 \rangle = -v_\Delta \) are

\[
\begin{align*}
\mu_H^2 &= -\frac{1}{2} M_{H\Delta} v_\Delta + \frac{1}{2} \lambda_{H\Delta} v_\Delta^2 + \cdots, \\
\mu_H^2 &= -\frac{1}{2} M_{H\Delta} v_\Delta + \frac{1}{2} \lambda_{H\Delta} v_\Delta^2 + \cdots.
\end{align*}
\]

where “\( \cdots \)” refers to terms not containing \( v_\Delta \). As a consequence, even with a positive \( \mu_H^2 \), the breaking of \( SU(2)_H \) with \( v_\Delta \neq 0 \) can trigger the breaking of \( SU(2)_L \) to give rise \( \langle H_1 \rangle \neq 0 \) if the sum of the second and third terms in (A8) can be sufficiently negative [38]. On the other hand, \( H_2 \), which does not develop a vev, can play a role for the inert Higgs doublet.

**Appendix B: Scalar mass spectra**

In the light of spontaneous symmetry breaking, we reparametrize the fields as

\[
H_1 = \left( \begin{array}{c} G^+ \\ \frac{v+h}{\sqrt{2}} + i \frac{G^0}{\sqrt{2}} \end{array} \right), \quad H_2 = \left( \begin{array}{c} H^+ \\ H^0 \end{array} \right), \quad \Phi_H = \left( \begin{array}{c} G^p_H \\ \frac{v+\phi_2}{\sqrt{2}} + i \frac{G^0_H}{\sqrt{2}} \end{array} \right), \quad \Delta_H = \left( \begin{array}{c} -\frac{v_\Delta + \phi_3}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \Delta_0 \end{array} \right).
\]

The scalar boson mass can be attained by taking the second derivatives of the potential in Eq. (A2) with respect to the corresponding scalar field, evaluated around the vacuum. There are mixing terms among the fields, depending on their quantum numbers. We start with a 3-by-3 mass matrix, consisting of three real scalars \( S = \{ h, \phi_2, \phi_3 \} \)

\[
\mathcal{M}_0^2 = \left( \begin{array}{ccc} 2\lambda_{H\Delta} & \lambda_{H\Delta} v_\Delta & \lambda_{H\Delta} v_\Delta \\ \lambda_{H\Delta} & 2\lambda_{H\Delta} & 2\lambda_{H\Delta} \\ \lambda_{H\Delta} & 2\lambda_{H\Delta} & 2\lambda_{H\Delta} \end{array} \right)
\]

This matrix can be diagonalized by an orthogonal matrix \( O \), defined as \( |f \rangle_i \equiv O_{ij} |m \rangle_j \) with \( i \) and \( j \) representing the flavor and mass eigenstates respectively,

\[
O^T \cdot \mathcal{M}_0^2 \cdot O = \text{Diag}(m_{h_1}^2, m_{h_2}^2, m_{h_3}^2).
\]

where the three eigenvalues are in ascending order. Since we focus on the situation of \( v_\Delta \sim v_\Phi \gg v \), the lightest eigenstate with mass \( m_{h_1} \) will be identified as the 125 GeV Higgs boson discovered at the LHC and the other two heavier Higgses \( h_2 \) and \( h_3 \) have the mass of \( m_{h_2} \) and \( m_{h_3} \). The observed 125 GeV Higgs boson is a mixture of the three neutral components \( h, \phi_2 \) and \( \delta_3 \).

The second mass matrix, comprised of three complex scalars \( G = \{ G^0_H, H^0, \Delta_p \} \), is

\[
\mathcal{M}_0^2 = \left( \begin{array}{ccc} M_{\Phi \Delta} v_\Delta + \frac{1}{2} \lambda_{H\Phi} v_\Phi & \frac{1}{2} \lambda_{H\Phi} v_\Phi & -\frac{1}{2} M_{\Phi \Delta} v_\Phi \\ \frac{1}{2} \lambda_{H\Phi} v_\Phi & M_{H\Delta} v_\Delta + \frac{1}{2} \lambda_{H\Delta} v_\Delta & \frac{1}{2} M_{H\Delta} v_\Delta \\ -\frac{1}{2} M_{\Phi \Delta} v_\Phi & \frac{1}{2} M_{H\Delta} v_\Delta & \frac{1}{4} v_\Delta (M_{H\Delta} v_\Delta^2 + M_{\Phi \Delta} v_\Phi^2) \end{array} \right).
\]

This matrix has a zero eigenvalue as can be seen by the vanishing determinant and by the eigenstate corresponding to the physical Goldstone bosons, \( \tilde{G}^{p,m} \sim v_\Phi G^{p,m} - v H^{0,0} + 2v_\Delta \Delta_{p,m} \). The other two eigenvalues are the masses of two physical complex fields \( \tilde{A} \) and \( D \) as

\[
M_\Delta^2 = \frac{-B \pm \sqrt{B^2 - 4AC}}{2A},
\]

with

\[
\begin{align*}
A &= 8 v_\Delta, \\
B &= -2 \left( M_{H\Delta} \left( v^2 + 4v_\Delta^2 \right) + M_{\Phi \Delta} \left( 4v_\Delta^2 + v_\Phi^2 \right) \\
&\quad + 2\lambda_{H\Phi} v_\Phi \left( v^2 + v_\Phi^2 \right) \right), \\
C &= \left( v^2 + 4v_\Delta^2 \right) \left( M_{H\Delta} \left( \lambda_{H\Phi} v_\Phi^2 + 2M_{\Phi \Delta} v_\Delta \right) \right.
\end{align*}
\]

The mass eigenstate \( D \) can be a DM candidate in G2HDM, accounting for the correct relic density [14]. Besides, there are four Goldstone boson fields \( G^\pm, G^0, \) and \( G^\pm_H \), with masses

\[
m_{G^\pm}^2 = m_{G^0}^2 = m_{G^0_H}^2 = 0,
\]

and a physical charged Higgs boson \( H^\pm \) with a mass

\[
m_{H^\pm}^2 = M_{H\Delta} v_\Delta - \frac{1}{2} \lambda_{H\Phi} v_\Phi^2 + \frac{1}{2} \lambda_{H\Delta} v_\Delta^2.
\]

The six Goldstone particles, \( G^\pm, G^0, G^0_H, \) and \( \tilde{G}^{p,m} \), will be absorbed by the longitudinal components of the massive gauge bosons \( W^\pm, Z, Z' \) and \( W^{(p,m)} \), respectively. As a result, one has two unbroken generators and two massless
gauge bosons left over after spontaneous symmetry breaking. One of them is naturally identified as the photon and the other one could play the role of either the light dark photon $\gamma_D$ or heavy $Z''$. To render the dark photon $\gamma_D$ or $Z''$ massive, one can either resort to the Stueckelberg mechanism or introduce yet another Higgs field $\Phi'$ solely charged under $U(1)_X$ to break one of the remaining two unbroken generators.

In this work, we confine ourselves to the scenarios with $m_{Z'} \lesssim m_{W^{(p,m)}} \lesssim 5 m_D$ and the heavy fermion masses of $\mathcal{O}(\text{TeV})$, which are determined by the new Yukawa couplings and $\langle \Phi_2 \rangle$: $m_{f H} = y'_f v_\Phi/\sqrt{2}$ ($f = d, u, e, \nu$) from Eq. (1). In order to realize the region of interest, $1.5 \lesssim m_{Z'} \lesssim m_{W^{(p,m)}} \lesssim 3 \text{ TeV}$, and avoid the LHC $Z'$ bounds shown in Fig. 1, from Eq. (3) the vevs of the $SU(2)_H$ doublet and triplet have to be

$$v_\Phi \gtrsim 40 \text{ TeV} \gtrsim 3 v_\Delta,$$

implying $y'_f \lesssim 0.1$. In Table 7, we present four different benchmark points: the second and third columns are for either Spectrum A or Spectrum B, while the last two columns are for either Spectrum A' or Spectrum B'. Recall that, on the one hand, Spectra A and A' are with lighter new quarks, while Spectra B and B' are with heavier new quarks. The required Yukawa couplings $y'_f$, for new fermions in G2HDM are of order $10^{-3}$ for Spectrum A (A') and order $10^{-2}$ for Spectrum B (B') which are quite acceptable. On the other hand, the mass spectrum of the Higgses is the same for Spectrum A and Spectrum B and for Spectrum A' and Spectrum B'. Similarly we have the cases for the mass spectrum of new gauge bosons. We should point out that the mass spectra displayed here are composed of points in the parameter space that satisfy the two theoretical constraints—the scalar potential is bounded from below and all relevant $2 \rightarrow 2$ scattering amplitudes among the scalars are below the unitarity bound. In addition to the theoretical constraints, we also impose the experimental constraints from the 125 GeV Higgs, including its mass and signal strengths decaying into diphoton and $\tau^+\tau^-$. A detailed study of these constraints on the scalar sector of G2HDM is presented in a separate work [38]. One should be aware that we choose a parameter space slightly different from that presented in Ref. [38] where the new gauge sector is much heavier than the Higgs sector. In this analysis, we choose the new gauge bosons $Z'$ and $W^{(p,m)}$ having masses between 1.5 and 3 TeV such that they are accessible at the LHC. Nevertheless the parameter space in the two works is chosen to satisfy the same set of aforementioned constraints.

### Table 7 Four benchmark points in the parameter space for the four mass spectra of interest in this work

| Input parameters | Spectrum A (B) | Spectrum A' (B') |
|------------------|---------------|------------------|
| $g_H$            | 0.08          | 0.08             |
| $\lambda_H$      | 0.149         | 0.786            |
| $\lambda_\Phi$   | 1.455         | 0.237            |
| $\lambda_\Delta$ | 4.557         | 2.840            |
| $\lambda_{\Delta H}$ | 0.616   | 0.346            |
| $\lambda_{H\Phi}$ | 0.360         | 0.570            |
| $\lambda_{H\Phi}'$ | 0.297         | 0.789            |
| $\lambda_{H\Phi}$ | 0.383         | 0.992            |
| $\lambda_{H\Phi}'$ | 0.383         | 0.992            |
| $M_{\Phi\Delta}$ (GeV) | 0.297         | 0.365            |
| $M_{H\Delta}$ (GeV) | 73.954        | 11.200           |
| $v$ (GeV)        | 246.000       | 246.000          |
| $v_\Phi$ (TeV)   | 67.329        | 48.521           |
| $v_\Delta$ (TeV) | 1.074         | 1.329            |

Mass spectrum

| $m_{b_1}$ (GeV) | 125.489 | 125.105 | 125.526 | 125.188 |
| $m_{b_2}$ (TeV) | 3.268  | 3.122  | 3.813  | 3.636  |
| $m_{\bar{b}_3}$ (TeV) | 114.855 | 33.414 | 92.125 | 104.584 |
| $m_{W^0}$ (TeV) | 29.465 | 34.172 | 58.312 | 37.462 |
| $m_D$ (GeV)     | 561.035 | 402.815 | 46.157 | 47.746 |
| $M_D$ (TeV)     | 29.465 | 34.173 | 58.312 | 37.462 |
| $m_{Z'}$ (TeV)  | 2.693  | 1.944  | 1.763  | 1.552  |
| $m_{W^{(p,m)}}$ (TeV) | 2.695  | 1.944  | 1.767  | 1.558  |

The gauge coupling $g_H$ is fixed to be either 0.08 or 0.04 in order to satisfy the Drell–Yan constraints, shown in Fig. 1.
