(Dated: July 18, 2018)

We theoretically investigate the transport properties of a weak coherent input field scattered by an ensemble of Λ-type atoms coupled to a one-dimensional photonic crystal waveguide. In our model, the atoms are randomly located in the lattice along the crystal axis. We analyze the transmission spectrum mediated by the tunable long-range atomic interactions, and observe the highest-energy dip. The results show that the highest-energy dip location is associated with the number of the atoms, which provides an accurate measuring tool for the emitter-waveguide system.

We also quantify the influence of a Gaussian inhomogeneous broadening and the dephasing on the transmission spectrum, concluding that the highest-energy dip is immune to both the inhomogeneous broadening and the dephasing. Furthermore, we study photon-photon correlations of the reflected field and observe quantum beats. With tremendous progress in coupling atoms to photonic crystal waveguides, our results may be experimentally realizable in the near future.

I. INTRODUCTION

In the past decades, realizing strong interactions between photons and atoms is of central importance for quantum optics and quantum information processing [1–4]. One primary method is to couple single atoms to high-finesse optical microcavities [5,6], i.e., cavity quantum electrodynamics (QED). Recently, one-dimensional (1D) waveguide provides another promising platform for photon-atom interactions [8–12]. In practice, a quasi-1D waveguide can be realized by a number of different systems, such as optical nanofibers [13,20], diamond waveguide [21,26], photonic crystal waveguide (PCW) [31], surface plasmon nanowire [32,36], and superconducting microwave transmission lines [37,40]. Due to nontrivial dispersion relation caused by the periodic dielectric structure, PCWs have attracted much attention. In the past decade, a great progress has been made to interface atoms or solid-state emitters with PCWs [47,60].

PCWs are periodic dielectric structures in which the field propagation can be drastically modified due to the photonic band gaps [51]. Recently, the atom-light interactions in PCWs have been explored, and rich phenomena are predicted to emerge. Particularly, when the transition frequency of an atom lies in a band gap, it can no longer emit a propagating photon into the dielectric structure. However, an evanescent field forms around the atomic position, which may be shown to exhibit the properties of an effective cavity mode. In turn, this cavity mode can mediate effective dipole-dipole interactions between different atoms, with a range and strength that may be tuned experimentally [59,62,67–69]. The combined atom-PCW system then represents a novel platform for the study of quantum many-body physics and non-linear optics [56,63,64].

Inspired by recent developments in coupling atoms to PCWs in experiment [51,58], we specifically study the dynamics of a weak coherent field propagating through a Λ-type atomic ensemble coupled to a 1D PCW. Since the precise manipulation of the atomic positions is challenging in interfacing atoms with PCWs in experiment, we consider the case that atoms are randomly placed in the lattice sites along the PCW. Here, we adopt the average values from a large sample of atomic spatial distributions and study the transport properties of the emitter-waveguide system.

In this work, we first study the transmission properties of a weak coherent input field and observe the highest-energy dip, which is different from the similar case in a conventional waveguide [70]. The results reveal that
the frequency of the highest-energy dip is related to the number of the atoms, which offers an experimental characterisation tool for the emitter-PCW system. We also analyze the influence of the inhomogeneous broadening in the atomic resonant transition, and quantify the effect of the dephasing in the two lower energy levels. We conclude that the highest-energy dip is immune to both the inhomogeneous broadening and the dephasing. Besides, since the number of the atoms located in the lattice sites may be not fixed in experiment, we study the transmission spectrum of the input field when the number of the atoms is drawn from a Poisson distribution. Under this condition, when the interaction length is much larger than the lattice constant, some almost equally spaced dips appear in the region around the maximum resonance frequency in the transmission spectrum, which via which we can infer the strength of the long-range atomic interaction. While, when the interaction length is of the order of the lattice constant, a broad dip appears in the transmission spectrum, and the maximum resonance frequency scales linearly with the mean number of the atoms. That is, even though the number of the atoms follows a Poisson distribution, we can also infer the mean number of the atoms from the maximum resonance frequency in the transmission spectrum. Finally, we calculate the photon correlation function of the reflected field at its maximum resonance frequency and observe strong initial bunching. Moreover, quantum beats emerge in the photon-photon correlation function of the reflected field, which arises from the long-range atomic interactions.

The paper is organized as follows. In Sec. II, we briefly review the physics of atoms coupled to a 1D PCW, and introduce an effective Hamiltonian for our system that an array of Λ-type atoms is coupled to a PCW. In Sec. III, we calculate the transmission properties of a weak coherent input field and analyze the influence of the inhomogeneous broadening and the dephasing. We also discuss the transport properties when the number of the atoms follows a Poisson distribution, and compute the photon-photon correlations of the reflected field. Finally, we summarize the main results and emphasize the advantage of our system in Sec. IV.

II. MODEL AND HAMILTONIAN

A PCW is a periodic dielectric material with regularly alternating refractive index [31, 71, 72]. For some frequencies, the light incident into the dielectric is reflected, and the PCW acts like a mirror. This results in the presence of band gaps in the dispersion relation, as shown in Fig. 1(a). The photonic structure supports multiple modes, e.g., the transverse-electric (TE) and transverse-magnetic (TM) modes. Here, we consider an array of Λ-type atoms randomly trapped in an optical lattice along the PCW with unit cell length a, as shown in Fig. 1(b). The atom has three relevant electronic levels, i.e., the ground state |g⟩, the metastable state |s⟩ and the excited state |e⟩. We assume that the resonance frequency ω0 of the transition |g⟩ ↔ |e⟩ with wavevector k∥ lies in the TE band gap, and is close to the lower band edge with detuning δ = ω∥ − ω0. In this case, due to the van Hove singularity in the density of states, the atomic transition |g⟩ ↔ |e⟩ is dominantly coupled to the PCW modes close to the lower band edge. In the effective mass approximation, the dispersion relation is quadratic ω∥ ≈ ω0(1 − α(k − k∥)2/k∥2), where k∥ = π/a is the wavevector at the band edge of the TE mode and α characterizes the band curvature [69]. Since the detuning to any other band edge is assumed to be much larger than δ, we can ignore their influence. When such an atom coupled to the PCW modes is excited at a frequency in the band gap, it will not radiate a propagating photon into the dielectric structure but seeds an exponentially decaying localized photonic cloud around the atom. It has been demonstrated that this photonic cloud has the same properties as a real cavity mode [59], which

![FIG. 1: (a) Schematic band structure of the TE and TM modes in a PCW, illustrating the guided mode frequency ωk versus the Bloch wavevector k. The atomic resonance frequency ω∥ (horizontal black dashed line) lies in the band gap (blue region) of the TE mode (black solid line), and is close to the lower band edge frequency ω∥ with detuning δ = ω∥ − ω0. (b) Schematic diagram for the transport of an incident field through an atomic chain (black dots) coupled to a PCW with unit cell length a. A coherent field (black arrow) is incident from left to scatter with the atomic chain, which produces a reflected field (red arrow) and a transmitted field (green arrow). The wavy line represents the optical lattice with periodicity d. Due to atomic collisions during the loading process [74], there exists either no atom or only one atom in each trap site [74].]
mediates the excitations exchange with other atoms via virtual photons. Since the band gaps of different modes occurs at different frequencies and $\omega_d$ is situated far from TM band gap, we may use the TM mode to probe the above long-range atomic interactions. We assume that the atomic transition $|g\rangle \leftrightarrow |e\rangle$ can couple with the TM mode via evanescent fields, and the single-atom coupling strength is denoted by $\Gamma_{1d}$. In addition, the transition $|e\rangle \leftrightarrow |s\rangle$ is driven by a classical control field with the Rabi frequency $\Omega_c$. The system composed of the atomic chain and the PCW can be described by an effective non-Hermitian Hamiltonian 56, 59, 63, 72

$$H_{\text{non}} = - \sum_j \left[ (\Delta + i\omega_d/2) \sigma_{ee}^j + (\Delta - \Delta_c) \sigma_{ss}^j \right] + \Omega_c (\sigma_{es}^j + H.c.) - i \sum_{j,k} 2^{\frac{\Gamma_{1d}}{2}} \sum_{j,k} e^{ik_0 |z_j - z_k|} \sigma_{ee}^j \sigma_{ge}^k \quad (1)$$

where $\Delta = \omega_{in} - \omega_a$ is the detuning between the frequency $\omega_{in}$ of the incident field with wavevector $k_{in}$ and the atomic resonance frequency $\omega_a$. $\Gamma_j$ represents the decay rate of the state $|e\rangle$ into free space, and $z_j$ is the position of the $j$th atom. $\Delta_c = \omega_c - \omega_{es}$ is the detuning between the frequency $\omega_c$ of the classical control field and the frequency $\omega_{es}$ of the atomic transition $|e\rangle \leftrightarrow |s\rangle$. $\mathcal{J}$ and $L$ denote the strength and characteristic length of the long-range interaction, respectively. We can tune the strength $\mathcal{J}$ and characteristic length $L$ by adjusting the band curvature near the lower band edge and the frequency detuning $\delta$ between the atomic transition and the band edge 57. In the last term of Eq. (1), we consider the self-interaction part ($j = k$), which can be compensated by an external potential in experiment 64.

Here, we study the transport of a continuous weak coherent incident field propagating through the atomic chain. The corresponding driving is described by $H_{\text{dri}} = \sqrt{\frac{\mathcal{J}}{2c}} \sum_{j} \left( \sigma_{ee}^j e^{ik_0 z_j} + \sigma_{ge}^j e^{-ik_0 z_j} \right)$, where $E$ is the amplitude of the weak input field 70. Thus, the properties of our system are govern by the total Hamiltonian $H = H_{\text{non}} + H_{\text{dri}}$, and the initial state is prepared in the global atomic ground state $|\psi_0\rangle = |g\rangle^{\otimes \mathcal{N}}$. When the input field is sufficiently weak, i.e., $\sqrt{\frac{\mathcal{J}}{2c}} E \ll \Gamma_{1d}$, quantum jumps can be neglected 67. Once the atomic dynamics are governed by the evolution under the Hamiltonian $H$, the transmitted ($T$) and reflected ($R$) fields can be recovered using the input-output relations 76

$$a_{\text{out},T}(z) = E e^{ik_0 z} + i \sqrt{\frac{\mathcal{J}}{2c}} \sum_{j} \sigma_{ee}^j e^{ik_0 (z - z_j)},$$

$$a_{\text{out},R}(z) = i \sqrt{\frac{\mathcal{J}}{2c}} \sum_{j} \sigma_{ge}^j e^{-ik_0 (z - z_j)}. \quad (2)$$

Therefore, the transmission of the weak incident field for the steady state is given by

$$T = \frac{\langle \psi | a^{\dagger}_{\text{out},T} a_{\text{out},T} | \psi \rangle}{E^2}, \quad (3)$$

where $|\psi\rangle$ is the steady-state wavevector. For the reflected field, the equation is similar.

### III. RESULTS

#### A. The transmission properties of the coherent input field

Here, we study the transmission spectrum of the weak input field for $n = 10$ three-level atoms randomly located in a lattice of $N = 200$ sites along a PCW, as shown in Fig. 2. In our simulations, we set the lattice constant $d$ to satisfy $k_d = \pi/2$, which minimizes reflection from the array 62, 63, 68, 70, 71. Assuming that the input field is monochromatic, we consider two cases: one is for $\mathcal{J} = 0$, i.e., a conventional waveguide, and the other is
for $J = 4\Gamma_e'$, i.e., a PCW. We find that, for a conventional waveguide ($J = 0$), electromagnetically induced transparency (EIT) phenomenon can be observed in the transmission spectrum, as shown in Fig. 2(a). This is the result of the complete destructive interference between two atomic transitions \cite{[22]}. While, for a PCW ($J \neq 0$), some new dips appear in the transmission spectrum due to the long-range interaction between atoms, which correspond to resonance frequencies of the system. Particularly, in the limit $L/d \to \infty$, e.g., $L = 10^4d$, we observe that the maximum resonance frequency is independent of the atomic spatial distributions. To interpret this, we can diagonalize the long-range atomic interaction term in the single excitation manifold. In fact, the $n \times n$ matrix has $(n - 1)$ degenerate resonance energies 0, and one largest resonance energy $nJ$. That is, we can use $nJ$ to evaluate the maximum resonance frequency $\omega_{\text{max}}$ approximately in the limit $L/d \to \infty$, i.e., $\omega_{\text{max}} \approx nJ$. As shown in Fig. 2(b), we give the values of $nJ$ and the maximum resonance frequency $\omega_{\text{max}}$ under the condition $L = 10^4d$. We observe that, the approximate estimation $\omega_{\text{max}} \approx nJ$ is valid. While for $1 \ll L/d \ll \infty$, since the maximum resonance frequency changes with the atomic spatial distribution, we adopt the average value from a large sample of atomic spatial distributions. As shown in Fig. 2(b), we give the relation between the maximum resonance frequency $\omega_{\text{max}}$ and the number $n$ of atoms for four cases, i.e., $L = 10^4d$, $L = 100d$, $L = 50d$ and $L = 20d$. We observe that, the maximum resonance frequency $\omega_{\text{max}}$ scales linearly with the number of the atoms in the three cases. Differently, for the same number of the atoms, the maximum resonance frequency $\omega_{\text{max}}$ increases with the characteristic length $L$ of the long-range atomic interaction, which can be interpreted by diagonalizing the long-range atomic interaction term. Thus, with the fixed parameters $L$, $N$ and $J$, we can infer the number $n$ of the atoms coupled to the PCW from the maximum resonance frequency $\omega_{\text{max}}$ in the transmission spectrum. Note that, the conclusions mentioned above still hold if the atomic resonance frequency is close to the upper band edge, but with opposite sign of the last term in Eq. (1). This provides an effective approach to change the sign of the long-range interactions by tuning the atomic resonance frequency close to either the upper or lower band edges. Since the highest-energy dip location in the transmission spectrum is related with the number of the atoms, we provide an accurate measuring tool for the emitter-waveguide system. In the following discussions, we will mainly focus on the condition $L = 100d$, which may be accessible in the ‘alligator’ PCW with state-of-the-art fabrication \cite{[54] [56] [59]}. However, our conclusions will be independent of specific choice of the characteristic length in the limit $L/d \gg 1$. While, for short-range interaction, e.g., $L/d \approx 1$, the coupling between distant atoms is very weak and the band gap interaction is negligible.

In above simulations, we assume that the A-type atoms located in the lattice are identical. However, in experiment, due to the off-resonant trapping fields for the atomic ensemble, the emitters trapped in different sites suffer different vector light shifts \cite{[13] [24]}. This effect may cause the inhomogeneous broadening in the atomic transition of the emitters. For simplicity, here we just consider the influence of the broadening in the $|e\rangle \leftrightarrow |s\rangle$ transition on the transmission spectrum. For concreteness, we consider that the inhomogeneous broadening is Gaussian with the probability density $\rho_{ih}(\Delta_{ih}) = \frac{1}{\sigma_{ih}\sqrt{2\pi}} \exp\left(-\frac{\Delta_{ih}^2}{2\sigma_{ih}^2}\right)$, where $\Delta_{ih}$ is the detuning from the expected frequency of the atomic transition $|e\rangle \leftrightarrow |s\rangle$ and $\sigma_{ih}$ being the standard deviation is a measure of the width of the inhomogeneous broadening. In each single-shot realization, we generate some random variables from the Gaussian probability density as the detuning of the atoms and a random set as the positions of the atoms, via which we calculate the transmission spectrum. As shown in Figs. 3(a) and 3(c), we give the transmission spectrum of the input field in three cases, i.e., $\sigma_{ih} = 0.5\Gamma_e'$, $2.0\Gamma_e'$, $5.4\Gamma_e'$. The results show that the maximum resonance frequency $\omega_{\text{max}}$ does not vary with the parameter $\sigma_{ih}$. We observe that, with the increment of the parameter $\sigma_{ih}$, the transmission $T_{\text{peak}}$ at the EIT-like peak decreases, which indicates that the inhomogeneous broadening destroys the destructive interference between the two atomic transitions $|s\rangle \leftrightarrow |e\rangle$ and $|e\rangle \leftrightarrow |s\rangle$. Interestingly, the transmission $T_{\text{dip}}$ at the maximum resonance frequency almost does not change with the parameter $\sigma_{ih}$. Moreover, we find that, when the parameter $\sigma_{ih}$ is sufficiently large, e.g., $\sigma_{ih} = 5.4\Gamma_e'$, the EIT-like
FIG. 4: The transmission spectrum of the coherent incident field as a function of the frequency detuning $\Delta/\Gamma'$ for (a) $\gamma_d = 0.5\Gamma'$, (b) $\gamma_d = 1.0\Gamma'$, (c) $\gamma_d = 5.5\Gamma'$. (d) The transmission $T_{peak}$ (black squares) at the EIT-like peak and the transmission $T_{dip}$ (green circles) at the maximum resonance frequency versus the dephasing rate $\gamma_d$. Solid line is an interpolated fit. (a)-(d) $n = 10$ atoms are randomly located in a lattice of $N = 200$ sites, and we average over 1000 samples of atomic spatial distributions with $\Gamma_{1D} = 0.3\Gamma'$, $\mathcal{E} = 0.0001\sqrt{\frac{\Gamma_{1D}^3}{2\pi}}$, $k_0d = \pi/2$, $a = d$, $\Delta_c = 0$, $L = 100d$, $\mathcal{J} = 4\Gamma'$, $\sigma_{ih} = 0$, and $\Omega_c = 2\Gamma'$.

peak will almost completely disappear, as shown in Fig. 3(c). For clear presentation, we give the transmission $T_{peak}$ at the EIT-like peak and the transmission $T_{dip}$ at the maximum resonance frequency as a function of the parameter $\sigma_{ih}$. As shown in Fig. 3(d), we find that the EIT-like peak are sensitive to the parameter $\sigma_{ih}$. While, the existence of the highest-energy dip is immune to the inhomogeneous broadening. That is, the property originating from the long-range atomic interaction term in Eq. 1 is not influenced by the inhomogeneous broadening of the transition $|e\rangle \leftrightarrow |s\rangle$. In other words, even though the parameter $\sigma_{ih}$ in the inhomogeneous broadening is much larger than the decay rate $\Gamma'$, we can also observe the highest-energy dip clearly in the transmission spectrum and acquire the maximum resonance frequency $\omega_{max}$.

In practical emitter-waveguide systems, the transport properties of the coherent input field may be influenced by the dephasing of the two lower energy levels. The dephasing rates of the atoms coupled to a PCW have not been reported yet. While, in a similar system, i.e., atoms trapped in the surface of the optical nanofibers, the dephasing of the two energy levels $|g\rangle$ and $|s\rangle$ exists due to temperature dependent light shifts in the optical trap $^{15}$, thermal motion of the atoms $^{22, 23}$ and atom-dependent Larmor precession caused by the residual magnetic field $^{50}$. For simplicity, we assume that the dephasing rates of all atoms are identical. The dynamics of the atomic system is governed by the master equation for the atomic density operator:

$$
\frac{d\rho}{dt} = -i[H_I, \rho] - \frac{\gamma_d}{2}\sum_j\left\{\{\sigma_{ee}, \rho\} - 2\sigma_{gg}\rho\sigma_{eg}\right\} \\
- \frac{\gamma_d}{2}\sum_j\left\{\{\sigma_{ss}, \rho\} - 2\sigma_{ss}\rho\sigma_{ss} + \{\sigma_{gg}, \rho\} - 2\sigma_{gg}\rho\sigma_{gg}\right\} \\
- \frac{\Gamma_{1D}}{2}\sum_{j,k}\cos(k_0|z_j - z_k|)(\rho\sigma_{gg}\rho + \rho\sigma_{gg}\rho) \\
- 2\sigma_{gg}\rho\sigma_{gg}. 
$$

(4)

where

$$
H_I = \sum_{j,k}\left[\Delta\sigma_{ee} + (\Delta - \Delta_c)\sigma_{ss} + \Omega_c(\sigma_{es} + H.c.)\right] \\
+ \mathcal{J}\sum_{j,k}\cos(k_0z_j)\cos(k_0z_k)e^{-i|z_j - z_k|/\ell}\sigma_{gg}\sigma_{gg} \\
+ \frac{\Gamma_{1D}}{2}\sum_{j,k}\sin(k_0|z_j - z_k|)\sigma_{gg}\sigma_{gg}.
$$

(5)

In Eq. 4, the third term on the right-hand side describes the dephasing of the two lower states $|g\rangle$ and $|s\rangle$. We assume that the dephasing rates of the two levels are the same and are given by $\gamma_d$. As shown in Fig. 4, we calculate the effect of the dephasing on the transmission spectrum. Here, we consider three choices of the dephasing rate, i.e., $\gamma_d = 0.5\Gamma'$, $1.0\Gamma'$, $5.5\Gamma'$. The results show that the maximum resonance frequency $\omega_{max}$
FIG. 6: (a) The transmission spectrum of the input field as a function of the frequency detuning \(\Delta/\Gamma_c\). (b) The mean spacing \(S\) between the adjacent dips as a function of the long-range interaction strength \(J\). (c) The transmission spectra of the input field in the region around the maximum resonance frequency for \(\bar{n}=10\) (red line), 20 (black line), 30 (blue line) with \(L=100d\). (d) The maximum resonance frequency \(\omega_{\text{max}}\) versus the mean number \(\bar{n}\) of atoms for \(L=200d\) (black circles), \(L=100d\) (blue squares) and \(L=50d\) (red asterisks). (a)-(b) The number of the atoms is drawn from a Poisson distribution of mean \(\bar{n}=10\) with \(L=10^4d\); (a) and (c)-(d) \(J=4\Gamma_c\); (a)-(d) we average over 30000 single-shot samples with the parameters \(\Gamma_{i,D}=0.3\Gamma_c\), \(\mathcal{E}=0.0001\sqrt{\frac{\Gamma_{e}}{2\pi}}\), \(N=200\), \(k_0d=\pi/2\), \(a=d\), \(\Delta_c=0\), \(\sigma_{ih}=0\), \(\gamma_d=0\), \(\gamma_{em}=0\), and \(\Omega_c=2\Gamma_c\).

FIG. 5: The results show that, some almost equally spaced dips appear in the region around the maximum resonance frequency for \(\bar{n}=10\) (red line), 20 (black line), 30 (blue line) with \(L=100d\). (c) The transmission spectra of the input field for four choices of the decay rate, i.e., \(\gamma_{em}=0.0001\Gamma_c^e, 0.001\Gamma_c^e, 0.01\Gamma_c^e, 0.1\Gamma_c^e\). The results show that the existence of the highest-energy dip is sensitive to the decay of the TE to TM modes. In detail, the decay rate \(\gamma_{em}\) is changed from 0.0001\(\Gamma_c^e\) to 0.01\(\Gamma_c^e\), the highest-energy dip will completely disappear. That is, to acquire the maximum resonance frequency \(\omega_{\text{max}}\) in the transmission spectrum, the decay of the TE to TM modes must be strongly suppressed.

In the discussion above, we have considered the dissipation via the decay of the atomic excited state into free space. While, for a realistic PCW in experiment, there probably also exists another one dissipation channel, i.e., the decay of the TE to TM modes [56]. Here, we assume that the decay rate of the TE to TM modes is given by \(\gamma_{em}\). As shown in Fig. 5 we give the transmission spectrum of the input field for four choices of the decay rate, i.e., \(\gamma_{em}=0.0001\Gamma_c^e, 0.001\Gamma_c^e, 0.01\Gamma_c^e, 0.1\Gamma_c^e\). The results show that the existence of the highest-energy dip is sensitive to the decay of the TE to TM modes. In detail, the decay rate \(\gamma_{em}\) is changed from 0.0001\(\Gamma_c^e\) to 0.01\(\Gamma_c^e\), the highest-energy dip will completely disappear. That is, to acquire the maximum resonance frequency \(\omega_{\text{max}}\) in the transmission spectrum, the decay of the TE to TM modes must be strongly suppressed.
maximum resonance frequency is related with the number of the atoms, i.e., \( \bar{n} \approx \eta \mathcal{J} \). Thus, in Fig. 7(a), each dip in the region around the maximum resonance corresponds to one random number drawn from the Poisson distribution. In other words, the difference between the numbers of the atoms corresponding to the adjacent dips is one, i.e., the frequency spacing between the nearest-neighbor dips is the strength \( \mathcal{J} \) of the long-range atomic interactions. To verify this conclusion, we calculate the mean spacing \( S \) between adjacent dips as a function of the strength \( \mathcal{J} \) of the long-range atomic interactions, as shown in Fig. 7(b). For comparison, we also plot the values of the strength \( \mathcal{J} \) that the mean spacing \( S \) between the adjacent dips is almost the same as the strength \( \mathcal{J} \). That is, under the condition \( L/d \to \infty \), one can obtain the strength \( \mathcal{J} \) of the long-range atomic interactions by calculating the mean spacing between adjacent dips in the transmission spectrum.

To proceed, we evaluate the transmission spectrum of the weak input field under the condition \( L = 100d \) when the number of the atoms follows a Poisson distribution. As shown in Fig. 7(c), we consider three cases, i.e., the mean numbers of the atoms are \( \bar{n} = 10, 20, 30 \), respectively. The results show that a broad dip appears in the region around the maximum resonance, which is different from the case \( L/d \to \infty \). Here, we denote the highest-energy dip location as \( \bar{\omega}_{\text{max}} \) when the number of the atoms follows a Poisson distribution. We observe that \( \bar{\omega}_{\text{max}} \approx \omega_{\text{max}} \) is valid in the three cases mentioned above. Moreover, we plot \( \bar{\omega}_{\text{max}} \) as a function of the mean number \( \bar{n} \) for three different interaction lengths, as shown in Fig. 6(d). We find that, the dip location \( \bar{\omega}_{\text{max}} \) (i.e., the maximum resonance frequency) scales linearly with the mean number \( \bar{n} \) of the atoms, which is similar to the case that the number of the atoms is fixed. That is, when the number of atoms follows a Poisson distribution, we can infer \( \bar{n} \) from the maximum resonance frequency \( \bar{\omega}_{\text{max}} \) in the transmission spectrum.

B. Photon-photon correlation

The key feature of non-classical light is the existence of correlations between photons, which can be characterized by the second-order correlation function \( g^{(2)} \) (also called photon-photon correlation function) [81]. For a weak coherent state, the photon-photon correlation function \( g^{(2)} \) of the output field is given by

\[
g^{(2)}(\tau) = \frac{\langle |\alpha_\gamma|^2 |\alpha_\gamma(\tau)\rangle \langle \alpha_\gamma(\tau)\alpha_\gamma^\dagger |\alpha_\gamma(\tau)\rangle |\alpha_\gamma(\tau)\rangle^2}{|\langle \alpha_\gamma(\tau)\rangle|^2}.
\]

Here, \( |\psi\rangle \) denotes the steady-state wavevector, and \( \alpha = T, R \).

Now, with a weak coherent incident field \( \sqrt{\frac{\bar{\omega}}{\omega}} \ll \Gamma \), we analyze the photon correlations of the output field at the corresponding maximum resonance frequency. As shown in Fig. 7, we compute the photon correlation function of the reflected field with two choices of the strength \( \mathcal{J} \) when \( n = 10 \) three-level atoms are randomly located in a lattice of \( N = 200 \) sites along a PCW. We find that, strong initial bunching appears in the reflected field in the two cases, i.e., \( g^{(2)}(t = 0) \gg 1 \). Since the reflected field originates purely from the scattering by the atomic ensemble, the strong initial bunching \( g^{(2)}(t = 0) \gg 1 \) indicates that the \( \Lambda \)-type atomic chain can scatter two photons simultaneously. Comparing Fig. 7(a) and Fig. 7(b), we conclude that the correlation properties of the reflected field is influenced by the strength \( \mathcal{J} \) of the long-range atomic interactions. That is, the initial bunching becomes stronger when we enhance the long-range interaction strength \( \mathcal{J} \). Furthermore, we observe quantum beats [2] in the second-order correlation function of the reflected field. Evidently, the stronger the long-range interaction, the more visible the quantum beats become. That is, the longer the atomic interactions in our system can cause the quantum beats in the photon-photon correlation function of the reflected field. The results reveal that our emitter-PCW system may provide an effective platform for experimental study of the nonclassical light.
IV. DISCUSSION AND SUMMARY

In our system, the PCW is mainly characterized by the parameters \( J \) and \( L \), which represent the characteristic strength and length of the long-range interaction, respectively. In practice, by tuning the detuning \( \delta \) from the band edge and band curvature \( \alpha \) at the band edge, one can control the parameters \( J \) and \( L \). In particular, the parameters \( J \) and \( L \) of the emitter-PCW system are given by \( J = \bar{g}_e^2/2\delta \) and \( L = \sqrt{\omega_0/k^2\delta} \), respectively. Here \( \bar{g}_e = g_L \sqrt{d/L} \), and \( g_L \) is the vacuum Rabi splitting. This could be due to scattering and absorption loss of the photonic crystal structure. With no decay of the TE to TM modes, the total effective dissipation rate of an excited atom is \( \Gamma_{\text{tot}} = \Gamma_{\text{die}} + \Gamma_{\gamma} + \kappa(\bar{g}_e/2\delta)^2 \). Here, the last term proportional to \( \kappa \) denotes the Purcell enhancement caused by the case that an atom is off-resonantly coupled to an effective cavity mode. In order to observe the phenomena arising from the long-range interaction mentioned above, the interaction strength \( J \) must exceed the total dissipation rate \( \Gamma_{\text{tot}} \). In fact, the ratio \( J/\Gamma_{\text{tot}} \) can be optimized by tuning the detuning \( \delta \). We find that, the theoretical maximum is \( J/\Gamma_{\text{tot}} = \sqrt{\bar{g}_e^2/\kappa \Gamma} \) when \( \delta^2 = \kappa \bar{g}_e^2/4\Gamma \), where \( \Gamma = \Gamma_{\text{die}} + \Gamma_{\gamma} \). Note that, optimizing the detuning \( \delta \) also changes the interaction length \( L = \sqrt{\omega_0/k^2\delta} \). In order to keep the length \( L \) fixed, we must also tune the band curvature \( \alpha \).

In a recent experiment \[50\], Hood et al. experimentally observed signatures of collective atom-light interactions by tuning the band edge frequency of the PCW relative to cesium atoms trapped along an alligator PCW. In their experiment, at the detuning \( \delta = 60\text{GHz} \) inside the band gap, the free space emission rate of the cesium atom is \( \Gamma_e/2\pi \approx 5.0\text{MHz} \), and the coupling strength between the TM modes and a single atom is \( \Gamma_{\text{die}}/\Gamma_e \approx 9.1 \times 10^{-3} \). Specifically, with lattice constant \( d = 370\text{nm} \), one finds that the characteristic strength and length of the long-range interaction are \( J/\Gamma_e \approx 0.182 \).\( L/d \approx 80 \), respectively. As shown in Fig. 4 of Ref. \[50\], they gave the ratio between the parameters \( J \) and \( \Gamma_{\text{die}} \) as a function of the detuning \( \delta \). While, their values of the parameters \( J \) and \( \Gamma_{\text{die}} \) are not yet good enough to observe the results shown in this paper. In additional to the alligator PCW, another possibility is to use a slot PCW \[14, 83\], which is obtained by placing two plasmon waveguides next to each other. By confining the emitters at the center of the nanostructure, one can get the values of \( J/\Gamma_e \approx 6, \Gamma_{\text{die}}/\Gamma_e \approx 0.3 \) for a detuning \( \delta = 20\text{GHz} \) from the band edge, and the range of atom-atom interaction is \( L/d \approx 80 \). In summary, to date, the emitter-PCW system has the curvature parameter \( 1.0 \leq \alpha \leq 10.6 \), giving the parameters \( 1.25 \leq J/\Gamma_e \leq 6.0 \) and \( 5 \leq L/d \leq 200 \) in current experiments \[53, 54, 56, 58\]. Thus, after optimizing the parameters of the emitter-PCW system, the values of \( J \) and \( L \) (i.e., \( J/\Gamma_e = 4, L/d = 100 \)) in our calculations fall well in the experimentally achievable limits. Note that, the case where \( L/d = 10^4 \) merely serves as an example for theoretical analysis of the phenomena. Nevertheless, we believe that there is a bright future for the setups yielding great improvement on these rates.

In summary, we have theoretically studied the transport properties of a Λ-type three-level atomic ensemble coupled to the band edge of a PCW. Considering the precise control of the atomic positions is still challenging in interfacing atoms with PCWs, we assume that atoms are randomly placed in the lattice along the axis of the PCW in our model. With the effective non-Hermitian Hamiltonian, we calculate the transmission spectrum of a weak coherent input field and observe the highest-energy dip, which arises from the long-range atomic interactions. We find that, in the limit \( L/d \gg 1 \), the maximum resonance frequency scales linearly with the number of the atoms coupled to the PCW, which may provide an accurate measuring tool for the emitter-PCW system. We also quantify the effect of a Gaussian inhomogeneous broadening of the transition \(|e⟩ ↔ |s⟩ \) and the dephasing in the two lower energy levels on the transmission spectrum. The results reveal that the existence of the highest-energy dip is immune to both the inhomogeneous broadening and the dephasing. Furthermore, we analyze the transmission spectrum of the weak input field when the number of the atoms follows a Poisson distribution. We find that, when the interaction length \( L \) is of the order of the lattice constant \( d \), a broad highest-energy dip appears in the transmission spectrum. That is, even though the number of atoms follows a Poisson distribution, we can infer the mean number \( \bar{n} \) of the atoms from the maximum resonance frequency. Finally, we calculate the photon-photon correlations of the reflected field at the maximum resonance frequency and observe strong initial bunching. Moreover, the long-range atomic interactions cause quantum beats in the photon-photon correlation function of the reflected field. We emphasize that, our work takes advantage of the emitter-PCW system that one can separately tune the range and strength of the atomic interactions by engineering the dispersion of the structure \[58, 62\]. In theory, the range of the atom-atom interaction is from effectively infinite to nearest neighbor \[58\]. Since tremendous progress has been made to experimentally realize the coupling between emitters and PCWs \[51, 54, 56, 58\], the results in our model may be realizable in the near future.
