Abstract. We report on the fusion of photons from two independent photonic crystal fiber sources into polarization entangled states using a fiber-based polarizing beamsplitter. We achieve fidelities of up to \( F = 0.74 \pm 0.01 \) with respect to the maximally entangled Bell state \( |\phi^+\rangle \) using a low pump power of \( 5.3 \) mW with a success rate of \( 3.2 \) fourfold detections per second. By increasing the pump power we find that success rates of up to \( 111.6 \) fourfold detections per second can be achieved, with entanglement still present in the fused state. We characterize the fusion operation by providing a full quantum process reconstruction. Here a model is developed to describe the generation of entanglement, including the main causes of imperfection, and we show that this model fits well with the experimental results. Our work shows how non-ideal settings limit the success of the fusion, providing useful information about the practical requirements for an operation that may be used to build large entangled states in bulk and on-chip quantum photonic waveguides.

1. Introduction

The controlled generation of quantum entanglement is an essential process for performing a wide range of tasks in the field of quantum information [1]. Quantum communication protocols such as teleportation [2], key distribution [3] and dense coding [4] all require the generation of entangled states. Entanglement is also generated during quantum computation [5] and in the simulation of many-body quantum systems [6]. So far, small-sized entangled states have been generated in a wide range of physical setups, with photonic systems representing one of the most promising due to their speed and flexibility. In recent years, much attention has been focused on generating multi-qubit entangled states such as cluster [7, 8], graph [9] and Dicke [10] states, as well as those with more unusual structures and correlations [11] in a probabilistic fashion. Schemes that allow for the deterministic generation of smaller two-qubit entangled states have also been realized [12–14], although low generation rates make these approaches challenging at present for building larger multi-qubit entangled states. Photonic setups that generate states probabilistically, although inherently non-scalable, provide a readily available test bed for probing the unique properties of quantum systems. Current experiments are, however, limited to entangled states of ten qubits or less [15]. Improving photon generation rates using new types of sources and understanding better the practical requirements for generating high-quality entanglement between these sources may open up access to even larger entangled states with more complex structures. This would enable the testing of quantum protocols and probing physical phenomena that only more sizable quantum systems are able to support.

In this work we report the first experiment to fuse photons from two independent photonic crystal fiber (PCF) sources into polarization entangled states. The fusion operation we demonstrate could be used to generate larger multi-qubit entangled states, such as cluster and graph states for use in future quantum photonic technologies [16], including quantum communication and computation. We also introduce a novel method to characterize the fusion process that could be applied to a variety of different setups, including bulk, waveguide and...
on-chip photonic systems. While the fusion process is probabilistic in our experiment, we comment on how it may be made deterministic in the long term for the purposes of building large scalable entangled quantum systems. Our PCF sources have a very high photon generation rate compared to commonly used nonlinear crystal sources [17]. Moreover, they make use of a zero-slope section of the phase-matching curve to produce photons in an intrinsically pure state, enabling good-quality quantum interference without the need for spectral filtering (with inherent loss), resulting in high count rates [17, 18]. We detect 90 000 coincidences per second from photon pairs produced with a pump laser power of 10.5 mW. In this context, we investigate the fusion of photons from two independent sources in detail and provide a full quantum process reconstruction. We do this by developing a theoretical model to describe the entangling operation that includes the main causes of imperfection between the photons being fused. We find that our model fits well with the experimental results. Our work shows how non-ideal settings limit the success of the fusion operation and provide detailed information about the practical requirements for using it to generate large multi-qubit entangled states in bulk [17, 18] and on-chip quantum photonic settings [19–23]. The fusion is performed with a fiber polarizing beamsplitter (FPBS), which is better suited than the bulk optics equivalent for integration into more complex schemes and scaling up to generate larger entangled states, where space constraints and coupling stability become important considerations. As it is waveguide-based, it is also interferometrically stable and well suited to the generation of resource states that are to be transmitted and received over fiber networks, for use in distributed quantum communication and networking protocols.

2. Experimental setup

Our setup for fusing photons from two independent PCF sources is depicted in figure 1. A Ti:sapphire laser emits 8 nm pulses at a wavelength of 724 nm with a repetition rate of 80 MHz, which are then filtered to 1 nm. The pulses are split at a 50:50 beamsplitter (BS) and rotated to horizontal polarization by half-wave plates (HWPs) in both arms, then passed through polarizing beamplitters (PBSs) and launched into the two PCFs. The fibers each produce a pair of photons (signal and idler) polarized orthogonally to the pump via four-wave mixing with non-degenerate wavelengths of 625 nm for the signals and 860 nm for the idlers. While these wavelengths can be tuned by changing the wavelength of the pump pulse, the photons are only emitted in an intrinsically pure state at this section of the phase-matching curve [17, 18]. A 90° twist in the fiber ensures that these photons exit the PCFs horizontally polarized, with an aspheric lens directing them into the PBSs, which transmit them. The PBS helps to filter out the pump pulses, which exit the fiber vertically polarized, and unpolarized background such as Raman scattering. An isolator (ISO) at the output of the laser, which allows only one-way transmission, blocks any reflected pulses from entering back into the laser. The photon pairs are then separated into different paths using dichroic mirrors (DMs). The separated idler photons pass through a long- and short-pass filter tilted to give a tunable transmission window of 4 nm full-width at half-maximum (FWHM), which transmits the idler while removing as much Raman background as possible. They are then collected in single-mode fibers followed by additional PBSs which remove background from reflected light in the PCFs. Multi-mode fibers are used to couple the idler to the detectors, where detections at D3 and D4 are used to herald the generation of the signal photons. The signal photons are rotated to diagonal polarization.
by HWPs and pass through a 40 nm FWHM bandpass filter. This bandwidth is large compared to the signal photon because the intrinsically pure state phase-matching makes narrow filtering unnecessary, and the filter only needs to remove any remaining light from the bright pump beam. They are then collected into single-mode fibers to guarantee optimal spatial overlap on the FPBS. Fiber polarization controllers (PCs) compensate for the effects on the polarization of strain-induced birefringence in the fibers. A quarter wave plate (QWP)–HWP–QWP chain on mode $2'$ compensates for any unwanted phase from the FPBS. Multi-mode fibers are used to couple the photons to the detectors. The detection of a photon at detector D1a (or D1b) with detector D2a (or D2b) together with detections at detectors D3 and D4 is used in a fourfold coincidence circuit to register a successful fusion. Here, the use of two detectors on each signal mode enables active filtering of higher-order photon emissions from four-wave mixing in the PCFs.

3. Fusion operation

The FPBS depicted in figure 1 transmits horizontal polarized photons (H) and reflects vertical polarized photons (V). Ideally it can be described by a unitary operation with respect to the reduced two-photon basis $\mathcal{T}_p := \{|HH\rangle, |HV\rangle, |VH\rangle, |VV\rangle, |(HV)0\rangle, |0(HV)\rangle\}$, where
\((HV)0\) \((0(HV))\) represents two photons of different polarizations in the first (second) mode and the vacuum, \(|0\rangle \equiv |\text{vac}\rangle\), in the second (first). In the case where we ‘monitor’ the number of photons present in the output ports, i.e. we gain information about the photon number but not the polarization, then the FPBS is described by the non-unitary trace-preserving channel \(E(\rho) = \sum_{i=0}^{1} \hat{E}_i \rho \hat{E}_i^\dagger\), with \(\sum_{i=0}^{1} \hat{E}_i^\dagger \hat{E}_i = 1\). Here the Kraus operator \(\hat{E}_0 = |HH\rangle\langle HH| + |VV\rangle\langle VV| + |HV\rangle\langle HV| + |VH\rangle\langle VH|\) describes an operation into the ‘coincidence basis’, or subspace of the Hilbert space with states having a single photon in each output mode \(C_b : = \{|HH\rangle, |HV\rangle, |VH\rangle, |VV\rangle\}\), where \(C_b \subset \mathcal{T}_p\). The second Kraus operator \(\hat{E}_1 = |0(HV)\rangle\langle HV| + |(HV)0\rangle\langle VH|\) describes an operation out of the subspace defined by the coincidence basis \(C_b\) and into a subspace of the basis \(\mathcal{T}_p\) with states having two photons in one of the output modes. As all operations are limited to the two-photon subspace defined by \(\mathcal{T}_p\), both \(\hat{E}_0\) and \(\hat{E}_1\) do not contain any basis states outside this subspace, such as \(|HH0\rangle\).

Furthermore, for input states restricted to the coincidence basis, one can drop the last two terms from \(\hat{E}_0\) and by monitoring the output of the FPBS in the coincidence basis alone, allowing these states to be transmitted, and by rejecting all other cases, one can also drop the \(\hat{E}_1\) operator to give the non-unitary non-trace-preserving channel \(E_b(\rho) = \hat{E}_0 \rho \hat{E}_0^\dagger\). This channel describes the combined action of the FPBS and monitoring in the coincidence basis with the Kraus operator

\[
\hat{E}_0 = |HH\rangle\langle HH| + |VV\rangle\langle VV|.
\]

This is a parity check operation [25, 26] in the sense that only states where both of the photons have the same polarization (even parity) are allowed to be transmitted. This operation can be used as a fundamental component in a variety of quantum protocols, such as quantum error correction [1], entanglement purification [26] and filtering [27, 28]. It also forms part of an efficient method to generate cluster state resources that can be used to carry out quantum computation [29]. Indeed, the parity check is used in Type-I fusion for efficiently building one-dimensional [30] and two-dimensional cluster states [30, 31] and can also be considered as a basic fusion operation; if successful, it matches Type-I fusion, but without the loss of any photons involved [8, 32]. In our experiment, however, in order to ‘monitor’ the output photon number in the coincidence basis we detect the photons by destroying them. Thus our parity check, or fusion operation, is a post-selected version and not scalable in its current form, unlike Type-I fusion [30]. This is due to an exponential decrease in the total success probability when using many of these operations. It should be noted that active monitoring in the coincidence basis without destroying the photons can be achieved in principle using a non-demolition-type measurement of the photon number [33], making this approach scalable using the techniques of [30]. However, such measurements require the photons to pass through media with a large nonlinear response at the single-photon level, which is technically challenging at present and beyond the scope of this paper [34].

Ideally, the FPBS channel \(E_b\) from equation (1) takes two photons in the state \(\rho_{\text{in}} = |in\rangle\langle in|\), with \(|in\rangle = |+\rangle |+\rangle\) and \(|+\rangle = \frac{1}{\sqrt{2}} (|H\rangle + |V\rangle)\), and fuses them into the maximally entangled state \(|\phi^+\rangle = (1/\sqrt{2}) (|HH\rangle + |VV\rangle)\), equivalent to a two-qubit cluster state under a local Hadamard rotation on the first qubit. The above fusion operation occurs with success probability \(p_0 = \text{Tr}(\hat{E}_0 \rho_{\text{in}} \hat{E}_0^\dagger) = 1/2\) due to the non-trace-preserving nature of the channel. Note that regardless of the success probability of a given input state \(\rho_{\text{in}}\) being transmitted into the coincidence basis,
the channel $E_F$ always acts with unit probability. Either a coincidence is measured and the input state is transmitted into the coincidence basis or no coincidence is measured and the input state is not transmitted into the coincidence basis. Moreover, if both photons represent the end qubits of two separate linear cluster states, as shown in figure 1(b), then after passing through the channel $E_F$ the cluster states are fused together; here the two linear cluster states involved are joined with one of the photons representing the middle qubit between the edges bonding to the two clusters and the other photon representing a qubit directly attached to it [9]. If failure occurs one tries again with the next qubits in both clusters [30]. Two-dimensional cluster states can also be formed using the channel $E_F$, as shown in figure 1(c), or in a scalable way based on the techniques of [30] and [31].

4. Fusion interference

In order to check that our FPBS is implementing the correct fusion operation $E_F$ and coherently interfering two input photons in the required spatio-temporal manner, we set the input state of the two signal photons to $|in\rangle = |+\rangle |+\rangle$ and modify a time delay $\delta \tau$ between the input photon pulses using a translation stage, as shown in figure 1. This allows us to maximize the coincidence probability temporally, with the FPBS single-mode input fibers ensuring good spatial overlap. At the detectors we measure the coincidence probability for the $|+\rangle |+\rangle$ state population, which for the expected entangled state $|\phi^+\rangle$ would give 1/2. However, the state $|\phi^+\rangle$ is produced from the fusion process acting on the input state $|in\rangle$ with a probability 1/2, so we expect the total coincidence probability to be 1/4. On the other hand, for an incoherent interference of the two photons, i.e. when $\delta \tau$ is larger than the mutual coherence time of the incoming photons $\tau_c$, but less than our detector coincidence time-window $\tau_{\text{coinc}}$, the probability for a coincidence is 1/8 upon considering all possible outcomes of the non-interfering photons. Thus, as we modify the time delay $\delta \tau$ in our setup, we look for an ‘antidip’ or peak in the coincidence probability (the number of coincidences). This is a Hong–Ou–Mandel-type interference effect [35] and a rigorous time-dependent derivation of the quantum interference phenomenon leading to this antidip in the coincidence probability is outlined in appendix A. Here one finds that the probability for a coincidence at a set time delay of $\delta \tau$ is given by

$$P_{\text{coinc}}(\delta \tau) = \frac{1}{8} \left(e^{-\frac{(\delta \tau/\sigma_t)^2}{2}} + 1\right),$$ (2)

where $\sigma_t$ is the pulse duration of the signal photon, defined as $2\sqrt{2 \ln 2}/\Delta \omega$, and $\Delta \omega$ is the FWHM of the signal’s spectral intensity. In our experiment $\sigma_t \approx 1$ ps and $\Delta \omega$ corresponds to $\Delta \lambda \approx 0.5$ nm. For complete temporal overlap $\delta \tau = 0$ and for coherent interference we expect a coincidence probability of 1/4. On the other hand, for large $\delta \tau$, $|\delta \tau| \gg \tau_c$, where $\tau_c \sim \sigma_t$, and with the coincidence time-window larger $\tau_{\text{coinc}} \gg |\delta \tau|$ we have incoherent interference and the coincidence probability drops to 1/8 as mentioned above.

In figure 2(a) we show the expected number of coincidences $N_{\text{coinc}}(\delta \tau)$ obtained from equation (2). Here, $N_{\text{coinc}}(\delta \tau) = N_{av} P_{\text{coinc}}(\delta \tau)$, where we have multiplied $P_{\text{coinc}}(\delta \tau)$ by the average number of counts in our experiment when $|\delta \tau| \gg \sigma_t$ in order to scale it correctly. We have $N_{av} = 401$. The function $N_{\text{coinc}}(\delta \tau)$ is plotted as the solid upper curve. In the lower dotted curve we include a possible frequency mismatch between the central frequencies of the two signal photons, $\omega_0^0$ and $\omega_0^1$, corresponding to $\Delta \lambda_m = 0.06$ nm coming from the spectral resolution of our spectrometer. This is calculated by carrying out the necessary integration over...
Figure 2. Coincidences and tomographic reconstruction of the density matrix for the fused state resulting from the input state $|+\rangle |+\rangle$. (a) Fourfold coincidences measured as a function of the delay time $\delta \tau$ (divided by the signal pulse duration $\sigma_t$) between the heralded signal photons, clearly showing the expected antidip around zero delay. Using a relatively low pump power of 5.3 mW per fiber in this case, we obtain 23 000 pair coincidences s$^{-1}$ per fiber and a maximum of 1.25 fourfold coincidences s$^{-1}$. The top curve is the ideal theoretical dependence and the dashed line includes a possible frequency mismatch corresponding to $\Delta \lambda_m = 0.06$ nm for the signal photons. The lower solid line is a best fit of the data to the function $N_{\text{av}}(p_0 e^{-(\delta \tau/\sigma_t)^2} + 1)/8$, finding $p_0 = 0.61$, and $N_{\text{av}}$ is the average number of counts in our experiment when $\delta \tau \gg \sigma_t$. (b) Experimental real part of the density matrix. (c) Experimental imaginary part. (d) Ideal real part for $|\phi^+\rangle$. (e) Ideal imaginary part for $|\phi^+\rangle$.

The data points from our experiment are also shown in figure 2(a), along with a best fit to the curve defined by $N_{\text{exp coinc}}(\delta \tau) = N_{\text{av coinc}}(\delta \tau)$, where $N_{\text{av coinc}}(\delta \tau) = (p_0 e^{-(\delta \tau/\sigma_t)^2} + 1)/8$, with $p_0 = 0.61$, giving an antidip visibility of 61%. Here, the visibility is defined as the percentage ratio of $(N_{\text{max coinc}} - N_{\text{min coinc}})/N_{\text{min coinc}}$. In our experiment we have $\tau_{\text{coinc}} = 3$ ns, $\tau_{\text{rep}} = 12.5$ ns and $\delta \tau$ is varied using a translation stage on the pump beam before entering one of the PCFs, as shown in figure 1(a). The errors are calculated using a Monte Carlo procedure with Poissonian fluctuations in the count statistics [37]. The main causes of deviation from the ideal case are the spectral mixedness of the signal photons from our sources [18], leading to broadening of the coincidence profile [36], and spatial mismatch between the interfering signal photons at the FPBS. We discuss later how these effects can be incorporated into our theoretical model. Note that photon loss, in general, affects the overall number of coincidences regardless of the time delay $\delta \tau$, leaving the visibility of the antidip unaffected.

In figures 2(b) and (c) we show a tomographic reconstruction of the experimentally fused entangled state of the two signal photons at $\delta \tau = 0$. This is obtained by measuring the qubits in
Table 1. Properties of the fused state as the pump power is increased.

| Power (mW) | Fourfold rate (s$^{-1}$) | Pairs per pulse | $F_{\varphi^+}$ | $C$   | $P$   |
|------------|--------------------------|-----------------|-----------------|-------|-------|
| 5.3        | 3.2                      | 0.037           | 0.740 ± 0.007   | 0.550 ± 0.014 | 0.63 ± 0.01 |
| 7.9        | 9.8                      | 0.064           | 0.677 ± 0.006   | 0.392 ± 0.012 | 0.520 ± 0.007 |
| 10.5       | 36.4                     | 0.103           | 0.606 ± 0.007   | 0.265 ± 0.015 | 0.448 ± 0.008 |
| 13.2       | 77.8                     | 0.160           | 0.554 ± 0.006   | 0.15 ± 0.01   | 0.392 ± 0.005 |
| 14.8       | 111.6                    | 0.193           | 0.520 ± 0.004   | 0.07 ± 0.01   | 0.359 ± 0.003 |

all combinations of the bases $\{|H/V\rangle, |+/-\rangle, |R/L\rangle\}$ [37]. Ideally, this state is the maximally entangled state $|\varphi^+\rangle$ shown in figures 2(d) and (e). At 3.2 fourfold coincidences per second our experimental state has a fidelity of $F_{\varphi^+} = 0.74 ± 0.01$ with respect to $|\varphi^+\rangle$, entanglement quantified by the concurrence of $C = 0.55 ± 0.01$ and a purity of $P = 0.63 ± 0.01$. Some background can be seen to be present in the state from the non-zero $|HV\rangle$ and $|VH\rangle$ terms in figure 2(b), which we attribute to higher-order photon emission, other background processes such as Raman scattering and imperfect polarization operations in our measurements. The background also gives rise to several non-zero terms in figure 2(c). In appendix B we analyze the effects of higher-order photon emission from the four-wave mixing process and find that at this count rate we expect the fidelity to be limited to $F_{\varphi^+} = 0.80$. By increasing the pump power to 14.8 mW we achieve a fourfold coincidence rate of 111.6 s$^{-1}$ with a fidelity of $F_{\varphi^+} = 0.520 ± 0.004$, a non-zero concurrence of $C = 0.07 ± 0.01$ and a purity of $P = 0.359 ± 0.003$. In table 1 we show how various parameters change as the pump power is increased and higher-order emission becomes increasingly significant. These generation rates and corresponding state properties show the potential of using PCFs for the controlled generation of larger multi-qubit entangled states for carrying out quantum protocols and investigating quantum phenomena with desired state qualities and success rates.

Spatial–temporal mode mismatch, loss and higher-order photon emission are sources of error leading to the deviation of our experimental data from the ideal case in both the coincidence probability and state tomography. While an explicit analysis of all factors leading to these effects is beyond the scope of this paper, we will show how it is possible to develop a theoretical model to describe the non-ideal fusion operation generating entangled states and connect it to the experimental antidip coincidence probability curve shown in figure 2(a).

5. Fusion process tomography

Ideally, our fusion operation should act as the non-trace-preserving channel $\mathcal{E}_F(\rho) = \hat{E}_0 \rho \hat{E}_0^\dagger$, with $\hat{E}_0$ defined in equation (1). However, as the experimental fusion is not ideal, we must find a more appropriate channel description. Assuming that polarization changes from input to output states are negligible (see figure 3(a)), we can write the experimental fusion operation as [28]

$$
\mathcal{E}_F^{\text{exp}}(\rho) = \sum_{n,m} \chi_{n,m}^F \hat{E}_n \rho \hat{E}_m^\dagger,
$$

(3)
Figure 3. Input and output states in the probing of the fusion operation. (a) Experimental coincidences for the $Z \rightarrow Z$ basis. (b) Ideal probability for the $Z \rightarrow Z$ basis. The fidelity $F_{Z \rightarrow Z}$ is given by the ratio of correctly transmitted photon pairs to the total number of transmitted pairs by the fusion operation for input basis $Z$ and output basis $Z$. Similarly for $F_{X \rightarrow X}$ and $F_{X \rightarrow Y}$. (c) Experimental coincidences for the $X \rightarrow X$ basis. (d) Ideal probability for the $X \rightarrow X$ basis. (e) Experimental coincidences for the $X \rightarrow Y$ basis. (f) Ideal probability for the $X \rightarrow Y$ basis. In all plots, each of the fourfold coincidence points was taken in 621s.

where the operators $\hat{E}_n$ are given as

$$
\hat{E}_0 = |HH\rangle\langle HH| + |VV\rangle\langle VV|,
$$

$$
\hat{E}_{zz} = |HH\rangle\langle HH| - |VV\rangle\langle VV|,
$$

$$
\hat{E}_{xy} = |HV\rangle\langle HV| + |VH\rangle\langle VH|,
$$

$$
\hat{E}_{xx} = |HV\rangle\langle HV| - |VH\rangle\langle VH|,
$$

(4)

which form an orthogonal operator set with respect to the Hilbert–Schmidt inner product. $\hat{E}_0$ is the ideal operation which occurs with probability $\chi^{F}_{0,0}$, the operator $\hat{E}_{zz}$ describes a phase flip error with probability $\chi^{F}_{zz}$, the operator $\hat{E}_{xy}$ describes leakage of odd-parity states ($|HV\rangle$ and $|VH\rangle$) through the fusion device with probability $\chi^{F}_{xy,xy}$ and, finally, the operator $\hat{E}_{xx}$ describes leakage and a phase flip with probability $\chi^{F}_{xx,xx}$. Thus we have $n, m \in \{0, zz, xy, xx\}$ and $\sum_n \chi^{F}_{n,n} = 1$. We can also define the basis fidelity [38] for input basis states $i$ and output
basis states $j$ as
\[ F_{i \rightarrow j} = \frac{1}{2} \sum_{i,k} \langle j_k | \mathcal{E}_F (|i_k \rangle \langle i_k|) | j_i \rangle, \tag{5} \]
where for $F_{Z \rightarrow Z}$ we have $\{|HH\}, |HV\}, |VH\}, |VV\} \rightarrow \{|HH\}, |VV\} \rangle$, for $F_{X \rightarrow X}$ we have $\{|++\}, |-+\rangle \rightarrow \{|++\}, |+-\rangle \rangle$ and $\{|+\}, |--\rangle \rightarrow \{|+\}, |+-\rangle \rangle$, for $F_{X \rightarrow Y}$ we have $\{|++\}, |-+\rangle \rightarrow \{|LR\}, |RL\} \rangle$ and $\{|+, |--\rangle \rightarrow \{|LL\}, |RR\} \rangle$. Substituting the above $i$ and $j$ basis states into equation (5) and using the orthogonality of the $\hat{E}_n$ operators appearing in $\mathcal{E}_F^{\text{exp}}$ of equation (3), the basis fidelities are found to be equivalent to the elements of the $\chi$ matrix as follows [28]:
\[
F_{Z \rightarrow Z} = \chi^F_{0,0} + \chi^F_{zz,zz}, \\
F_{X \rightarrow X} = \chi^F_{0,0} + \chi^F_{xx,xx}, \\
F_{X \rightarrow Y} = \chi^F_{0,0} + \chi^F_{xy,xy}. \tag{6}
\]
From these we then have the relation for the process fidelity of the fusion operation, $F_p^{\text{exp}} \equiv \chi^F_{0,0}$, describing the probability for successful fusion as
\[ F_p^{\text{exp}} = \frac{1}{2} (F_{Z \rightarrow Z} + F_{X \rightarrow X} + F_{X \rightarrow Y} - 1), \tag{7} \]
where we have used $\sum_n \chi^F_{n,n} = 1$. The basis fidelities can be found from our experiment using the relation
\[ F_{i \rightarrow j} = \frac{\sum_{i,k} N_{i,j}^{\text{out}}}{\sum_i T_i}, \tag{8} \]
as described in appendix C. Here, $N_{i,j}^{\text{out}}$ is the number of times the output state is measured to be $|j_i\rangle$ when the input state $|i_k\rangle$ is sent through the device and $T_i = \sum_{j} N_{i,j}^{\text{out}}$. Equation (8) essentially means that we can define the basis fidelities $F_{i \rightarrow j}$ to be the ratio of the total number of transmitted output states in the correct basis to the total number of transmitted states. In figure 3 we show the experimentally measured number of transmitted states (coincidences) for the input and output basis defined by the fidelities $F_{Z \rightarrow Z}$, $F_{X \rightarrow X}$ and $F_{X \rightarrow Y}$. We find $F_{Z \rightarrow Z} = 0.958 \pm 0.001$ from the data shown in figure 3(a), with the ideal transmission coincidence probabilities for $Z \rightarrow Z$ shown in figure 3(b). From the data corresponding to figure 3(c), we find $F_{X \rightarrow X} = 0.768 \pm 0.001$. The ideal transmission coincidence probabilities for $X \rightarrow X$ are shown in figure 3(d). Finally, from the data corresponding to figure 3(e) we find $F_{X \rightarrow Y} = 0.759 \pm 0.001$, with the ideal transmission coincidence probabilities for $X \rightarrow Y$ shown in figure 3(f). From these three fidelities we then find, using equation (7), a process fidelity of our fusion operation of $F_p^{\text{exp}} = 0.743 \pm 0.001$.

The entanglement capability of our fusion operation can be defined as the maximum entanglement that can be generated from it using input product states. We can quantify this in terms of the concurrence $C$ and we have the lower bound for the entanglement capability of the fusion operation, quantified by the concurrence as $C_E \geq 2F_p^{\text{exp}} - 1$, as shown in appendix D. Based on the above process fidelity of our experiment, we have $C_E \geq 0.485 \pm 0.002$. Note that both $F_p^{\text{exp}}$ and $C_E$ are consistent with the fidelity and concurrence calculated directly from the reconstructed density matrix of the last section for the rate of 6.62 events per second at $\delta \tau = 0$. A small deviation is due to the assumption of no polarization change from input to output states in the model used to describe the experimental fusion process $\mathcal{E}_F^{\text{exp}}$. 

New Journal of Physics 14 (2012) 023021 (http://www.njp.org/)
6. Non-ideal temporal setting

So far we have considered our fusion operation at the maximum visibility $\delta \tau = 0$. In the ideal case of $\delta \tau = 0$, we have that the state $|+\rangle_1 |+\rangle_2$ is transformed into the entangled state $|\phi^+\rangle_{1'2'}$ with probability $1/2$. However, for $|\delta \tau| \gg \tau_c$ we obtain the incoherent mixture $\rho = \frac{1}{2} (|HH\rangle\langle HH| + |VV\rangle\langle VV|)_{1'2'}$ with probability $1/2$. Here, the photon in mode $1'$ is detected before the photon in mode $2'$ (or vice versa) and even though the time period $|\delta \tau|$ is outside the coherence time of the individual photons $\tau_c$, the larger coincidence window $\tau_{\text{coinc}}$ means that we still register the state as being a valid output state from the fusion process. This loss of coherence in the output state suggests that the process might be described by a phase damping channel acting on the output photons. This can be incorporated into the fusion channel by writing the total action of the fusion as $\mathcal{E}_T(\rho_{in}) = \mathcal{E}_{PD}(\mathcal{E}_F(\rho_{in}))$, where $\mathcal{E}_{PD}$ is a phase damping channel, the form of which we derive next. The same channel might also describe other forms of decoherence, such as that resulting from imperfect spatial-mode overlap or spectral distinguishability between the interfering photons. These parameters are challenging to set in an experiment, so it is useful to understand how the fusion operation performs under such conditions. By developing a model that describes the effect of non-ideal control, we may then quantify the requirements for a given level of performance of the fusion.

For a single qubit, a phase damping channel with an arbitrary time-dependent dephasing function $f(\delta \tau) \in [0, 1]$ can be described by the channel $\mathcal{E}(\rho) = \sum_{i=0}^1 \hat{K}_i \rho \hat{K}_i^\dagger$, with the Kraus operators

\[
\hat{K}_0 = \frac{1}{\sqrt{2}}[(1 + f(\delta \tau))]^{1/2} \mathbb{1}, \\
\hat{K}_1 = \frac{1}{\sqrt{2}}[(1 - f(\delta \tau))]^{1/2} \sigma_z,
\]

which satisfy $\hat{K}_0^\dagger \hat{K}_0 + \hat{K}_1^\dagger \hat{K}_1 = \mathbb{1}$. Usually, the function $f(\delta \tau) = e^{-\Gamma \delta \tau}$ is considered, where $\Gamma$ represents some decay rate and $\delta \tau$ is a positive exposure time. Here we wish to determine the form of $f(\delta \tau)$ for our fusion operation initially using $\delta \tau$ as the temporal parameter. Considering two qubits subject to such a type of arbitrary phase damping, we have the overall channel $\mathcal{E}_{PD}(\rho) = \sum_{i=0}^{3} \hat{K}_i \rho \hat{K}_i^\dagger$, where

\[
\hat{K}_0 = \alpha^2 \mathbb{1} \otimes \mathbb{1}, \\
\hat{K}_1 = \alpha \beta \mathbb{1} \otimes \sigma_z, \\
\hat{K}_2 = \alpha \beta \sigma_z \otimes \mathbb{1}, \\
\hat{K}_3 = \beta^2 \sigma_z \otimes \sigma_z,
\]

with $\alpha = [(1 + f(\delta \tau))/2]^{1/2}$ and $\beta = [(1 - f(\delta \tau))/2]^{1/2}$. We can now write the total channel $\mathcal{E}_T(\rho) = \mathcal{E}_{PD}(\mathcal{E}_F(\rho))$ describing the non-ideal fusion and phase damping due to $\delta \tau \neq 0$ in the $\{\hat{E}_n\}$ basis as

\[
\mathcal{E}_T(\rho) = \sum_{\ell,n,m} \chi_{\ell,n}^F \hat{E}_\ell \rho \hat{E}_\ell^\dagger \hat{K}_n^\dagger \hat{\chi}_{n,m}^T \hat{E}_m \hat{E}_m^\dagger.
\]

The second equality is possible because $\mathbb{1}$ and $\sigma_z$ do not change the polarization, so that we can rewrite the combined operators more conveniently in terms of only $\hat{E}_0$, $\hat{E}_{zz}$, $\hat{E}_{xx}$, $\hat{E}_{yy}$, and the
elements of a new matrix $\chi^T$ using the identities $\mathbb{1} \otimes \mathbb{1} \equiv \hat{E}_0 + \hat{E}_{xy}$, $\mathbb{1} \otimes \sigma_z \equiv \hat{E}_{zz} - \hat{E}_{xx}$, $\sigma_z \otimes \mathbb{1} \equiv \hat{E}_{zz} + \hat{E}_{xx}$ and $\sigma_z \otimes \sigma_z \equiv \hat{E}_0 - \hat{E}_{xy}$. In particular, we have that the total success probability for the fusion operation is given by $F^T_\delta = F_{0,0}^T = (\alpha^4 + \beta^4)\chi_{0,0}^F + (2\alpha^2 \beta^2)\chi_{zz,zz}^F$. Substituting in for $\alpha$ and $\beta$, with $f(\delta \tau)$ arbitrary, we have

$$F^T_\delta = \frac{1}{2}(\chi_{0,0}^F + \chi_{zz,zz}^F) + \frac{1}{2} f(\delta \tau)^2(\chi_{0,0}^F - \chi_{zz,zz}^F). \quad (11)$$

Similarly, we have

$$\chi^T_{zz,zz} = \frac{1}{2}(\chi_{0,0}^F + \chi_{zz,zz}^F) - \frac{1}{2} f(\delta \tau)^2(\chi_{0,0}^F - \chi_{zz,zz}^F),$$

$$\chi^T_{xx,xx} = \frac{1}{2}(\chi_{xx,xx}^F + \chi_{yy,yy}^F) + \frac{1}{2} f(\delta \tau)^2(\chi_{xx,xx}^F - \chi_{yy,yy}^F),$$

$$\chi^T_{xy,xy} = \frac{1}{2}(\chi_{xx,xx}^F + \chi_{yy,yy}^F) - \frac{1}{2} f(\delta \tau)^2(\chi_{xx,xx}^F - \chi_{yy,yy}^F). \quad (12)$$

We can find the expected form of the phase damping function $f(\delta \tau)$ by considering the coincidence probability $P_{\text{coinc}}$ given in equation (2) for the case of ideal fusion. Here, the fusion operation acts on the state $|+\rangle |+\rangle$ and produces the state

$$\rho = \frac{1}{2}[(|HH\rangle \langle HH| + |HH\rangle \langle VV| + |VV\rangle \langle HH| + |VV\rangle \langle VV|], \quad (13)$$

with probability 1/2. After phase damping we then end up with the state $\rho' = \rho_{PD}(\rho)$ given by

$$\rho' = \frac{1}{2}[(|HH\rangle \langle HH| + f(\delta \tau)^2|HH\rangle \langle VV| + f(\delta \tau)^2|VV\rangle \langle HH| + |VV\rangle \langle VV|]. \quad (14)$$

Measuring the population of $\rho'$ in the state $|+\rangle |+\rangle$ gives $(1 + f(\delta \tau)^2)/4$. By including the factor of 1/2 due to the probabilistic nature of the fusion producing the state in equation (13), we have that $P_{\text{coinc}} = (1 + f(\delta \tau)^2)/8$. Using equation (2) we are able to then make the correspondence $f(\delta \tau) = e^{-(\delta \tau/\sigma_\tau)^2/2}$. In figure 4(a) we show the expected dependence of the total process fidelity $F^T_\delta$ and entanglement capability with the time delay $\delta \tau$ in the case of our experimental fusion at $\delta \tau = 0$. The data give a close match to the expected dependence. For definiteness we choose positive $\delta \tau$ with the temporal dependence being symmetric. In both of these we have used the phase damping function $f(\delta \tau) = e^{-(\delta \tau/\sigma_\tau)^2/2}$.

In figure 4(b), we show the $\chi^T$ matrix elements for the total process of fusion and phase damping, as defined in equations (11) and (12). The solid lines correspond to the expected dependence of the ideal fusion with phase damping and the dotted lines correspond to the expected dependence of our experimental fusion at $\delta \tau = 0$ with phase damping applied. In both, the phase damping function is $f(\delta \tau) = e^{-(\delta \tau/\sigma_\tau)^2/2}$. Again, the data closely match the $f(\delta \tau)$ model. Note that for ideal fusion, the elements $\chi^T_{xx,xx}$ and $\chi^T_{xy,xy}$ are zero always, regardless of the amount of phase damping. However, figure 4(b) shows that this is not the case for non-ideal fusion, as in our experiment. Note also from figure 4(b) that in the case of our experimental fusion at $\delta \tau = 0$, the effects of imperfections such as spectral mixedness and spatial mismatch can be almost entirely described in terms of an ideal fusion operation (solid lines) that has been phase damped. Indeed, at $\delta \tau/\sigma_\tau \simeq 1$ in figure 4(b), one can see that the phase-damped ideal fusion matches the non-damped experimental fusion at $\delta \tau = 0$. Thus to a good approximation ($\chi^T_{xx,xx}$ and $\chi^T_{xy,xy}$ negligible), we can model our experimental fusion operation at $\delta \tau = 0$ as being a phase damped ideal fusion operation. For $\delta \tau > 0$ an additional phase damped channel with the function $f(\delta \tau)$ is then applied to each qubit.
Figure 4. The total process fidelity, entanglement capability and elements of the process matrix. (a) The total process fidelity $F_T^p$ and entanglement capability $C_E$ dependence on the time delay $\delta \tau$. The solid (dotted) line shows the decay expected from the theoretical phase damping model with the experimental fusion values taken at zero time delay for $F_T^p (C_E)$. The experimental values are plotted as triangles (circles), with errors negligible on the scale of the graph. (b) The elements of the total process matrix $\chi_T^T$ as they depend on the time delay $\delta \tau$. The upper (lower) solid line corresponds to the element $\chi_{0,0}^T (\chi_{zz,zz}^T)$ from the theoretical model with perfect fusion. The upper (lower) dashed line corresponds to the element $\chi_{0,0}^T (\chi_{zz,zz}^T)$ from the experimental data at $\delta \tau = 0$ extrapolated using the function $f(\delta \tau)$. The lower lines show the elements $\chi_{xx,xx}^T$ and $\chi_{xy,xy}^T$. For ideal fusion these are zero regardless of the time delay. The experimental values are plotted as circles, triangles, squares and diamonds for 00, zz, xx and yy, respectively, with errors negligible on the scale of the graph. Note that all diagonal $\chi_T^T$ elements sum to one regardless of the time delay $\delta \tau$.

7. Summary

In this paper we have reported an experimental demonstration of the fusion of photons from two independent PCF sources into polarization entangled states. We introduced and carried out a novel method to characterize the fusion operation via quantum process reconstruction. To do this we developed a theoretical model to describe the entangling process which included the main imperfections. We then showed that our model fitted well with the experimental results. This paper highlights the need for accurate control of spatial and temporal properties for the success of photonic fusion and provides detailed information about the practical requirements and limitations of an operation that may be used in emerging quantum photonic technologies. Future work will aim to optimize our fusion operation and use it to generate larger high-quality multi-qubit entangled states, including the use of additional degrees of freedom such as path and frequency encoding, for carrying out computations and communication protocols.

New Journal of Physics 14 (2012) 023021 (http://www.njp.org/)
Appendix A. Derivation of fusion interference antidip

Starting from the initial state $|H\rangle_1 |H\rangle_2$ for the signal photons in modes 1 and 2, produced from the PCF sources as shown in figure 1, and finishing with the measurement of the coincidence probability for the state $|H\rangle_1 |H\rangle_2$ at the detectors $D1a$ and $D2a$, we have the probability density for a photon to be detected in mode $1a$ at time $t_0$ and another in mode $2a$ at time $t_0 + \tau$ given by

$$P_{\text{coinc}}(t_0, \tau) = 12 \langle HH | \hat{E}_{H}^{-} (t_0) \hat{E}_{H}^{+} (t_0 + \tau) \hat{E}_{H}^{-} (t_0 + \tau) \hat{E}_{H}^{+} (t_0) |HH\rangle_{12}$$

(A.1)

where the scalar photon-unit time-dependent electric field operators are defined as

$$\hat{E}_i^+(t) = \frac{1}{\sqrt{2\pi}} \int d\omega \ e^{-i\omega t} \hat{a}_i(\omega),$$

$$\hat{E}_i^-(t) = \frac{1}{\sqrt{2\pi}} \int d\omega \ e^{i\omega t} \hat{a}_i^+(\omega)$$

(A.2)

with $\hat{a}_i^+(\omega)$ and $\hat{a}_i(\omega)$ being the photon creation and annihilation operators, respectively, which obey the bosonic commutation relation $[\hat{a}_i(\omega), \hat{a}_j^+(\omega')] = \delta_{ij}(\omega - \omega')$. The initial state $|HH\rangle_{12}$ is written as

$$|HH\rangle_{12} = \int \! d\omega_1 \int \! d\omega_2 \ \phi_1(\omega_1) \phi_2(\omega_2) \hat{a}_{H_1}^+(\omega_1) \hat{a}_{H_2}^-(\omega_2) |0\rangle,$$

(A.3)

where $\phi_i(\omega_i)$ is the spectral amplitude of a single-photon pulse in mode $i$, normalized so that $\int \! d\omega \phi_i^*(\omega) \phi_i(\omega) = 1$. The initial state $|H\rangle_1 |H\rangle_2$ is rotated into the required input state $|+\rangle_1 |+\rangle_2$ of the FPBS by HWPs that produce the transformations $\hat{a}_{H_1}^+(\omega_1) \rightarrow (1/\sqrt{2})[\hat{a}_{H_1}^+(\omega_1) + \hat{a}_{V_1}^+(\omega_1)]$ and $\hat{a}_{H_2}^+(\omega_2) \rightarrow (1/\sqrt{2})[\hat{a}_{H_2}^+(\omega_2) + \hat{a}_{V_2}^+(\omega_2)]$. The action of the FPBS, combined with the HWP–QWP–HWP chain on mode 2 (for phase correction), produces the transformations

$$\hat{a}_{H_1}^+(\omega_1) \rightarrow \hat{a}_{H_2'}^+(\omega_1),$$
$$\hat{a}_{V_1}^+(\omega_1) \rightarrow i\hat{a}_{V_2'}^+(\omega_1),$$
$$\hat{a}_{H_2}^+(\omega_2) \rightarrow \hat{a}_{H_2'}^-(\omega_2),$$
$$\hat{a}_{V_2}^+(\omega_2) \rightarrow -i\hat{a}_{V_2'}^-(\omega_2).$$

(A.4)

Next, the HWP and QWP on each mode produce the transformations

$$\hat{a}_{H_1'}^+(\omega_1) \rightarrow (1/\sqrt{2})[\hat{a}_{H_1'}^+(\omega_1) + \hat{a}_{V_1'}^+(\omega_1)],$$
$$\hat{a}_{V_1'}^+(\omega_1) \rightarrow (1/\sqrt{2})[\hat{a}_{H_1'}^+(\omega_1) - \hat{a}_{V_1'}^+(\omega_1)],$$
$$\hat{a}_{H_2'}^-(\omega_2) \rightarrow (1/\sqrt{2})[\hat{a}_{H_2'}^-(\omega_2) + \hat{a}_{V_2'}^-(\omega_2)],$$
$$\hat{a}_{V_2'}^-(\omega_2) \rightarrow (1/\sqrt{2})[\hat{a}_{H_2'}^-(\omega_2) - \hat{a}_{V_2'}^-(\omega_2)].$$

The PBSs that follow produce the transformations

$$\hat{a}_{H_1'}^+(\omega_1) \rightarrow \hat{a}_{H_{1u}}^+(\omega_1),$$
$$\hat{a}_{V_1'}^+(\omega_1) \rightarrow i\hat{a}_{V_{1b}}^+(\omega_1),$$
$$\hat{a}_{H_2'}^-(\omega_2) \rightarrow \hat{a}_{H_{2u}}^-(\omega_2),$$
$$\hat{a}_{V_2'}^-(\omega_2) \rightarrow -i\hat{a}_{V_{2b}}^-(\omega_2).$$
Thus, only horizontally polarized photons will be detected at detectors $D1a$ and $D2a$. These last operations (the HWP, QWP and PBS) together with the detections in modes $1a$ and $2a$ are equivalent to measuring the coincidence probability for the state $|+\rangle_1 |+\rangle_2$ in the output of the fusion. Therefore $P_{\text{coinc}}(t_0, \tau)$ in equation (A.1) represents the coincidence probability density for the state $|+\rangle_1 |+\rangle_2$.

Substituting all the above transforms into equation (A.3), then substituting this into equation (A.1) with the definitions given in equation (A.2) and carrying out the necessary integrations [36], one finds

\[ P_{\text{coinc}}(t_0, \tau) = \frac{1}{16} \left| \zeta_1(t_0 + \tau) \zeta_2(t_0) + \zeta_1(t_0) \zeta_2(t_0 + \tau) \right|^2, \]  

(A.5)

where $\zeta_i(t) = \frac{1}{2\pi} \int d\omega_i \phi_i(\omega_i) e^{-i\omega_i t}$ is the spatio-temporal modefunction for mode $i$. Choosing Gaussian single-photon pulses for each of the input modes, with a time delay of $\delta\tau$ between the peaks of the pulses, we have

\[ \zeta_1(t) = (2/\pi)^{1/4} e^{-t^2 - i\omega^0_1 t}, \]  

(A.6)

\[ \zeta_2(t) = (2/\pi)^{1/4} e^{-t^2 - i\omega^0_2 t}. \]  

(A.7)

Here, $\omega^0_i$ is the central carrier frequency for mode $i$ expressed in units of $1/\sigma_i$ and the times $t$ and $\delta\tau$ are expressed in units of $\sigma_i$ ($\sigma_i$ is the pulse duration of the signal photon, defined as $2\sqrt{2\ln 2}/\Delta\omega_i$, and $\Delta\omega_i$ is the full-width at half-maximum of the signal’s spectral intensity). Substituting these expressions into equation (A.5) and integrating over all possible detection times $t_0$, i.e. $\int_{-\infty}^{\infty} dt_0$, one finds the probability density for a coincidence at a time duration $\tau$ with a set delay of $\delta\tau$ given by

\[ P_{\text{coinc}}(\tau, \delta\tau) = \frac{e^{-\delta\tau^2 - \tau^2}}{\sqrt{64\pi}} (\cos[(\omega^0_1 - \omega^0_2)\tau] + \cosh[2\delta\tau \tau]). \]  

(A.8)

Setting the central carrier frequencies the same for the moment, $\omega^0_1 = \omega^0_2$, we then integrate equation (A.8) with respect to $\tau$ over the coincidence window. Here, the integration is $\int_{-t_{\text{coinc}}/2}^{t_{\text{coinc}}/2} d\tau$, allowing for either signal photon to be detected first. For $\tau_{\text{rep}} > t_{\text{coinc}} \gg |\delta\tau|$, where $\tau_{\text{rep}}$ is the time between the pump pulses (and therefore possible signal photons produced from four-wave mixing in the PCFs), one finds the coincidence probability

\[ P_{\text{coinc}}(\delta\tau) = \frac{1}{8} (e^{-(\delta\tau/\sigma_i)^2} + 1), \]  

(A.9)

where we have now included $\sigma_i$ explicitly. Although we have neglected a time-dependent evaluation of the idler photons in the above analysis, they can also be included. Indeed, it is straightforward to check that such a calculation does not change the result of equation (A.9), given that the idler photons are assumed to be in a product state with the signal photons.

**Appendix B. Higher-order emission analysis**

The state generated by four-wave mixing in one source can be written as [39]

\[ |\psi\rangle = \mathcal{N} (|0, 0\rangle_{s,i} + \alpha |H, H\rangle_{s,i} + \alpha^2 (2H, 2H)_{s,i} + O(\alpha^3)), \]  

(B.1)

where $\mathcal{N}$ is a normalization constant and $|\alpha|^2 = \bar{n}$ is the mean number of signal–idler pairs generated in a pulse. When the idler detector registers a click, the heralded density matrix of the
signal mode becomes
\[ \rho_s = \text{Tr}_i \left( \frac{\Pi_{\text{click}}^{1/2} \langle \psi | \Pi_{\text{click}}^{1/2} \rangle}{\text{Tr}(\Pi_{\text{click}} | \psi \rangle \langle \psi |)} \right), \]  
\hspace{1cm} \text{(B.2)}

where the action of the detector is described by the positive operator-valued measure \( \{ \Pi_{\text{click}}, \Pi_{\text{no-click}} = 1 - \Pi_{\text{click}} \} \), with \( \Pi_{\text{click}} = \sum_{n=0}^{\infty} (1 - (1 - \eta)^n) |nH\rangle \langle nH| \) and \( \eta \) is the lumped detector efficiency of registering a click given that a single photon is input into the mode it monitors. From equation (B.2) we have
\[ \rho_s = \mathcal{N}(\eta_1 |H\rangle \langle H| + 2\eta_2 |2H\rangle \langle 2H| + O(\eta^2)), \]  
\hspace{1cm} \text{(B.3)}

where \( \eta_n = 1 - (1 - \eta)^n \). We now write the heralded state of the two sources to first-order in \( \eta \) as
\[ \rho_{12} = \mathcal{N}(|H\rangle \langle H| + 2\eta |H\rangle \langle 2H| + 2\eta |2H\rangle \langle H| + 2\eta |2H\rangle \langle 2H| + O(\eta^2)), \]  
\hspace{1cm} \text{(B.4)}

where \( \gamma = \eta_2/2\eta_1 \). The signal photons from \( \rho_{12} \) are first rotated from horizontal to diagonal polarization and then input to the FPBS. Using the transformations given in equation (A.4) of appendix A, we can write the output from the FPBS by making the following substitution in equation (B.4):
\[ |nH, mH\rangle_{12} \rightarrow \frac{(\hat{a}_{H_x}^+ + i\hat{a}_{V_y}^+)^n (\hat{a}_{H_x}^- - i\hat{a}_{V_y}^-)^m}{2^{(n+m)/2} \sqrt{n!m!}}, \]  
\hspace{1cm} \text{(B.5)}

where we have now switched from the Schrödinger to the Heisenberg picture. By removing the terms which do not lead to a possible coincidence of detection clicks between the two signal modes, then performing the polarization rotations used in analyzing each measurement basis \( \{ |H/V\rangle, |+/-\rangle, |R/L\rangle \} \) and switching back into the Schrödinger picture to determine the contribution to the coincidence counts of the \( O(\eta) \) terms in equation (B.4), we can evaluate the effects of higher-order emissions in our data. For instance, we find that the visibility of the antidip in figure 2, up to \( O(\eta) \), is limited to
\[ \rho_0 = \frac{1 - 4\eta \gamma + 6\eta^2 \gamma^2}{1 + 6\eta \gamma + 3\eta^2 \gamma^2}. \]  
\hspace{1cm} \text{(B.6)}

In addition, for the lowest power in table 1 where \( \eta = 0.037 \), taking \( \eta = 0.1 \) and considering up to \( O(\eta) \) terms, the expected fidelity of the output state with respect to \( |\phi^+\rangle \) is \( F_{\phi^+} = 0.80 \). This assumes that the fusion process is ideal, and so represents an upper bound.

**Appendix C. Derivation of basis fidelities**

The basis fidelities can be found from our experiment by noting the relation
\[ \langle j_{\ell} | \mathcal{E}_F^{\text{exp}}(|i_k\rangle \langle i_k|) | j_{\ell} \rangle = \frac{N_{i_k,j_{\ell}}^{\text{out}}}{N_{i_k}^{\text{in}}}, \]  
\hspace{1cm} \text{(C.1)}

where \( N_{i_k}^{\text{in}} \) is the number of times input state \( |i_k\rangle \) is sent through the device and \( N_{i_k,j_{\ell}}^{\text{out}} \) is the number of times the output state is measured to be \( |j_{\ell}\rangle \) when input state \( |i_k\rangle \) is sent through the device. We then have that
\[ F_{i \rightarrow j} = \frac{1}{2} \sum_{\ell,k} \frac{N_{i_k,j_{\ell}}^{\text{out}}}{N_{i_k}^{\text{in}}}. \]  
\hspace{1cm} \text{(C.2)}

*New Journal of Physics* **14** (2012) 023021 (http://www.njp.org/)
Keeping the value of $N_{i_k}^{\text{in}}$ constant over the experiment for all possible input states $|i_k\rangle$, i.e. $N_{i_k}^{\text{in}} = N_{i_k}^{\text{in}}$, and noting that $\text{Tr}(E_{\text{F}}^{\exp}(1/4)) = 1/2$ for any experimental process matrix $\chi$ appearing in equation (3), we have that $N_{i_k}^{\text{in}} = \sum_{i_k} T_{i_k}$, where $T_{i_k} = \sum_{i_k} N_{i_k}^{\text{out}}$. In other words, for a given input basis $i$, the total number of transmitted states over that basis is equal to half the total number of input states (in this case $2N_{i_k}^{\text{in}}$). Therefore we have

$$F_{i\rightarrow j} = \frac{\sum_{i_k} N_{i_k,j_k}^{\text{out}}}{\sum_{i_k} T_{i_k}}. \quad (C.3)$$

**Appendix D. Relation of concurrence to fusion operation fidelity**

The concurrence, $C$, for a two-qubit state $\rho_{12}$ can be written as [40]

$$C(\rho_{12}) = \max \left\{ 0, - \min_{A \in \text{SL}(2,\mathbb{C})} \text{Tr}((|A\rangle\langle A|)^{\frac{1}{2}} \rho_{12}) \right\}, \quad (D.1)$$

where $|A\rangle$ denotes the unnormalized state $(A \otimes \mathbb{1}) |I\rangle$, with $|I\rangle = \sum_i |ii\rangle$ and $A$ is any matrix with $\det(A) = 1$. In equation (D.1) any choice for the state $|A\rangle$ provides a lower bound on the concurrence, thus choosing $|A\rangle = \sqrt{2} |\psi_-\rangle$, we have that $(|A\rangle\langle A|)^{\frac{1}{2}} = \mathbb{1} - 2|\phi^+\rangle\langle \phi^+|$, and we can rewrite equation (D.1) as

$$C(\rho_{12}) \geq \max\{0, 2F_{\phi^+} - 1\}, \quad (D.2)$$

where $F_{\phi^+} = \text{Tr}(|\phi^+\rangle\langle \phi^+| \rho_{12})$ is the fidelity of the state $\rho_{12}$ with respect to $|\phi^+\rangle$. If we consider the state $\rho_{12}$ to be an output state from a channel $E$ acting on two input product states, then $C(\rho_{12})$ provides a lower bound on the entanglement capacity of that channel. Choosing the input product state to be $\rho_{\text{in}} = |+\rangle\langle +| \otimes |+\rangle\langle +|$ and the channel to be our experimental fusion operation $E_{\text{F}}^{\exp}$, we have that $\rho_{12} = E_{\text{F}}^{\exp}(\rho_{\text{in}}) = F_{\phi^+}^{\exp}|\phi^+\rangle\langle \phi^+| + (1 - F_{\phi^+}^{\exp}) \rho'$. Thus, $F_{\phi^+} = F_{\phi^+}^{\exp}$ and we have the lower bound for the entanglement capability of the fusion operation, quantified by the concurrence as $C_E \geq 2F_{\phi^+}^{\exp} - 1$.
