RESEARCH ARTICLE

Dental erosion in French adolescents

Michèle Muller-Bolla1,2*, Frédéric Courson2,3, Violaine Smail-Faugeron2,3, Thibault Bernardin1 and Laurence Lupi-Pégurier1

Abstract

Background: Since the 2000s, different epidemiological studies focusing on the prevalence or the aetiology of DE in adolescents recognised them as an at-risk population due to their eating behaviours. None was carried out in French adolescents.

The primary objective of this study was to assess the prevalence of dental erosion (DE) using the total BEWE score among adolescents in the department of Alpes Maritimes, France. The secondary objectives were to observe changes in prevalence estimates depending on both the cutoff value of total BEWE score with different teeth/dental surfaces examined, and to identify the related risk factors.

Methods: A cross-sectional study in a multi-stage random sample of 339 14-yr-old schoolchildren was carried out in 2014. The children completed a self-administered questionnaire concerning diet and oral habits. Caries was assessed with ICDAS-II (International Caries Detection and Assessment System-II) criteria and erosion with BEWE (Basic Erosive Wear Examination) index. The total BEWE score was calculated to assess the DE prevalence with two cutoff values (3 and 1). Data were analysed using descriptive statistics and logistic regression models.

Results: The 331 children were aged 14.4 ± 0.5 years. The DE prevalence was 39 % using a total BEWE score ≥ 3. With a cutoff total BEWE score of 1 (at least one affected tooth), the prevalence varied from 3.9 to 56.8 % depending on the teeth/surfaces that were used for the analysis. The DE prevalence, assessed with only first molars and maxillary incisors, was about 54 %. The risk factors for DE (total BEWE score ≥ 3) were daily consumption of acidic beverages (OR: 4.0; 95 % CI: 2.1–7.6) and acidic sweets (OR: 3.2; 95 % CI: 1.2–8.0), low socio economic category (OR: 2.4; 95 % CI: 1.1–5.0) and visible dental biofilm (OR: 2.0; 95 % CI: 1.2–3.4).

Conclusion: Depending on the method chosen, the prevalence varied from 3.9 to 56.8 % among these adolescents. Thus, a consensus on choice of index, teeth to examine and age at assessment is necessary to standardise measurement of DE prevalence.

Background

Dental erosion (DE) is a non-carious lesion consisting of progressive and irreversible loss of dental hard tissue due to the chemical process of acid dissolution that does not involve bacterial plaque acid [1, 2]. Its overall clinical appearance may also involve a frictional component, such as abrasion or attrition, particularly in older age groups. Since the 2000s, different epidemiological studies focusing on the prevalence or the aetiology of DE in adolescents recognised them as an at-risk population due to their eating behaviours. The studies were carried out in the Americas [3–14], Arabian countries [15–23], an Asian country [24, 25] and in Western Europe [2, 26–35]. The prevalence of DE ranged from 7 to 95 % and, except in two studies, the extension of severe erosion into dentine was usually infrequent [11, 16] (Table 1). The wide variation of prevalence in teenagers is suggestive of the difficulty in finding a unanimously accepted index among researchers for measuring and detecting erosive lesions. A recent systematic review estimated an overall worldwide prevalence of tooth erosion of 30 % (95 % CI: 24–37) by mixing different clinical indices and without specifying the teeth examined. Furthermore, the review included population-based studies in

B Buccal, I Incisal, P Palatal, L Lingual, O Occlusal, UI upper incisors, UC upper canines, M1 first molars, UK United Kingdom, BEWE Basic Erosive Wear Examination
the permanent teeth of children and adolescents aged 8–19 years [36].

When focusing on Europeans adolescents, the prevalence of DE has ranged from 18 to 64 % [28, 33] but no epidemiological study of DE has so far been carried out in France (Table 1). The prevalence of DE was only indirectly considered in the study of Bartlett et al. [37]; it focused on the prevalence of tooth wear in 18–35 year-old Europeans including France and six other countries. The index used to measure both severity and distribution of tooth wear was the Basic Erosive Wear Examination (BEWE), as recommended by different authors [1, 38–41] but the protocol did not consider all surfaces, just the buccal and lingual surfaces of all teeth [37]. Nevertheless early signs of erosion are often observed on the occlusal surfaces of molars [1]. The problem of which clinical index to use and which teeth and tooth surfaces to observe arises since many different methods are available in the literature (Table 1). Finally, no studies that address the risk indicators for DE in France have been found.

The primary objective of the present study was to assess the prevalence of DE using the total BEWE score in a sample of French adolescents. The secondary objectives were to observe changes in prevalence depending on both the cutoff value of total BEWE score on different teeth/dental surfaces examined, and to identify the related risk factors.

Methods
This cross-sectional survey was carried out in 2014 in the Alpes Maritimes (AM) department in the south-east of France. Ethical approval was obtained from the local ethics committee (“Comité Protection Personnes sud Méditerranée V”).

Study population
Alpes Maritimes is the 14th most densely populated department in France with 251 persons per sq km. It includes Nice, the fifth largest city in France. Four of the 71 public secondary schools are located in rural areas, the others are in urban areas where students enrolled in priority education schools (PES) (12.5 %) are of lower socioeconomic status than others.

Sampling procedure
A minimum sample size of 322 adolescents was required assuming prevalence of DE of 30 % [42, 43], precision and level of statistical significance of 0.05. We used a two-stage, stratified sampling method to obtain a representative sample of approximately 14-yr-old adolescents from 8th grade high-schools by randomisation of the schools on the basis of geographic location (urban/rural) and socio-economic category (PES/not PES). A list of all the schools was obtained from the local education department. Firstly, a consent form to participate in the study was given to all of the parents prior to the dentist’s visit to the randomised schools. Secondly, the children who were present on the day of the examination and for whom positive parental and personal consent was obtained were included. Children were excluded if they were not 14 years old during the school year or if they were currently wearing orthodontic appliances. Children affected by a hereditary or acquired dental structural abnormality were also excluded.

Data collection
The data were collected on the day of the examination using a self-completed questionnaire. This questionnaire was based on one used in previous studies that identified risk factors for DE [44] and included sociodemographic characteristics, dietary and oral health behaviours. The French version was first tested in 30 French 14-yr-olds and it was found to be comprehensible for this age group.

Clinical examinations
Before examination, with good lighting (Power-Spotlight, Bisico, France), the teeth were carefully cleaned (Happy morning brushes, Hager & Werken, France) and dried (Trans’Care Max, Satelec group, Acteon equipment, France). Lesions were scored using the BEWE index (0 = no erosion, 1 = early enamel surface loss, 2 = enamel and dentine surface loss < 50 %, 3 = surface loss 50 %) on all permanent tooth scoreable surfaces. With this scoring system, all teeth were examined, and the most severely affected surfaces (buccal/labial, occlusal, and lingual/palatal) in each sextant were recorded. Each subject obtained a total BEWE score that corresponded to the sum of the highest scores in the six sextants; and the prevalence of erosion was calculated on the basis of a total BEWE score ≥ 3. The risk level of DE is low when the total score is between 3 and 8; medium, between 9 and 13; and high for a score of 14 and above [38, 39, 41]. Carious lesions were recorded using the ICDAS-II (International Caries Detection and Assessment System) advanced method on all scoreable surfaces of permanent teeth. Children were affected by dentinal lesions (ICDAS 4–6) or with both enamel and dentinal lesions (ICDAS 1–6) [45]. After the examination, the children received a card to take home reporting their dental needs.

All clinical examinations were carried out by a single examiner (TB) who was trained and calibrated by a paediatric dentist (MMB). A range of different levels of dental erosion was used in the calibration process, which was based on photographic images. Reliability was assessed through the Kappa test.
Statistical analysis
Prevalence was estimated as the proportion that had a total BEWE score $\geq 3$ considering highest scores in sextants (primary outcome). The proportions with a total BEWE score $\geq 1$ on particular permanent teeth (incisors, canines, first molars) were secondary outcomes. Data analysis included comparisons of means and the Chi-squared test to investigate the univariate associations between the dichotomous dependent variable DE (primary outcome) and a range of demographic, dietary and oral care variables. Independent variables which were associated with DE ($p < 0.1$) were entered as candidate variables into a stepwise multiple logistic regression analysis. All the significant variables were ranked using a multivariable logistic regression analysis. Similar multivariable logistic regression analyses were tested, changing the cutoff value of the dependent variable (total BEWE score $\geq 1$ considering all surfaces). The level of statistical significance was set at 0.05. In each classroom, one child chosen at random was examined twice one week later by the same examiner using the ICDAS-II advanced method and the BEWE index to measure intra-examiner reliability. The corresponding Kappa values assessed in 34 re-examined children one week later were respectively 0.8 (ICDAS-II) and 0.9 (BEWE). Data were analysed using SPSS19.0.

Results
Of the 495 subjects invited to participate, 143 did not return the parental consent, 3 were absent on the day of the visit dates and 18 were excluded. The 331 children were aged 14.4 ± 0.5 years. There were 174 girls and 157 boys included; 12.1 % ($n = 40$) were enrolled in PES and 5.1 % ($n = 17$) in rural schools.

The highest total BEWE score $\geq 3$ (cumulative score of all sextants) in our study was in the range 9–13 (medium risk level) for only one adolescent. When the total BEWE cutoff score was $\geq 3$, prevalence was 39 % (primary objective). When the cut off value was 1, i.e. at least one tooth with signs of DE, the prevalence depended on the dental surfaces observed. If only maxillary incisors were examined, as in the method used in some studies carried out in adolescents [7, 12, 23] (Table 1), the prevalence decreased from 39 to 3.9 %. Conversely, if first molars were examined in addition to the maxillary incisors, whatever the surfaces considered, the prevalence was about 54 %, close to 56.8 % for all the surfaces examined on all permanent teeth (Table 2).

\begin{table}
\centering
\caption{Dental Erosion prevalence in a sample of French adolescents ($n = 331$) according to the dental surfaces of permanent teeth examined.}
\begin{tabular}{lll}
\hline
Dental surfaces examined & BEWE & Prevalence \\
\hline
Maxillary incisors $^a$ & Total BEWE $\geq 1$ & 3.9 % \\
Maxillary incisors and occlusal surfaces of first molars $^b$ & Total BEWE $\geq 1$ & 54.4 % \\
Maxillary incisors and first molars on all scorable surfaces $^c$ & Total BEWE $\geq 1$ & 54.4 % \\
Incisors and first molars $^d$ & Total BEWE $\geq 1$ & 55.0 % \\
Six upper and lower anterior teeth, occlusal surfaces of first molars $^e$ & Total BEWE $\geq 1$ & 55.0 % \\
All teeth (all surfaces) $^f$ & Total BEWE $\geq 1$ & 56.8 % \\
\hline
\end{tabular}
\end{table}

and score 2 was found on occlusal surfaces of permanent molars and second premolars. First molars, and more particularly the lower ones, were the most affected teeth (Table 3). If we consider the results for each kind of tooth, 98.0 % of the subjects with at least one second molar affected by DE presented also DE on the first molars. Second premolars were more often affected than both the first ones and the second molars.

The risk factors for DE (Total BEWE score $\geq 3$) were, in decreasing order, the consumption of acidic beverages and sweets, and the low socio-economic category of participants. Area of residence, the presence of carious lesions (ICDAS 1–6 or 4–6) and prolonged retention of drinks in the mouth were not significantly associated with erosive experience in adjusted logistic regression analyses; visible dental biofilm was only associated if lesions ICDAS 4–6 were included in the multivariable logistic regression analysis (Table 4). Thus the consumption of acidic beverages (OR: 4.0; 95 % CI: 2.1–7.6) and sweets (OR: 3.2; 95 % CI: 1.2–8.0), low socio-economic category (OR: 2.4; 95 % CI: 1.1–5.0) and the presence of visible dental biofilm (OR: 2.0; 95 % CI: 1.2–3.4) had an effect on the primary outcome. When changing the dependent variable by substitution of primary outcome with the total BEWE score $\geq 1$ considering all surfaces, independent variables which were entered as candidate variables into a stepwise multiple logistic regression analysis were different (Table 5). With this cutoff value, only acidic beverages (OR: 6.4; 95 % CI: 2.9–14.0) and drinking method (OR: 3.5; 95 % CI: 1.4–8.9) had an effect on the dependant variable.

Discussion
The prevalence of DE using a total BEWE score $\geq 3$ in a stratified sample of French adolescents was 39 %. This was within the confidence interval of the overall estimated
prevalence of DE in European countries (33 %, 95 % IC 25–42) and outside the confidence interval of the overall worldwide prevalence of DE of 30 % (95 % IC: 24–37), both reported in a recent systematic review [36]. Except in the two studies carried out in the United States [3, 13, 14], prevalences in America ranged from 7.2 to 34.1 % and were lower than in France [4–12] whereas the systematic review, which included fewer studies, did not indicate any significant difference between American and European countries [36]. Conversely, except for the two studies with equivalent rates [15, 17, 19–21], four descriptive studies carried out in Arab countries indicated a higher prevalence, ranging from 51 to 95 % [16, 18, 22, 23]. Finally, by increasing order of prevalence in European countries, France was situated between The Netherlands [30, 33, 34] and Iceland [2, 29], with rates around 20–30 %, and United Kingdom [26–28, 31, 32] or Greece [35] around 50–60 %.

This ranking by country must be considered with caution as the prevalence of DE in adolescents was studied using different clinical indices. As indicated in the systematic review of Salas et al. [36], the prevalences of DE assessed with O’Sullivan’s or Lussi’s modified scales were lower [2, 4, 7, 8, 11, 17, 24, 29, 30, 33, 34] than in the present study using the total BEWE score. On the contrary, the prevalences of DE were higher with the Tooth Wear Index (TWI) modified three times (Table 1). One of them [31] easily explains these observations because this was dichotomised as the presence or absence of dentinal exposure [22, 26, 27, 31]. In the present study, the erosive lesions involved mostly the enamel. Only the study of Hamasha et al. [15], that used the TWI modified by Millward, did not confirm this result due to the lower prevalence. In France, the prevalence was assessed with BEWE total score because it is now both the most recommended index and the more recently used, especially in adults [35, 39, 41, 46, 47]. In children and adolescents, this was only used in a retrospective study [40] and in a study with a population-based sample mixing adults and adolescents [48]. However, three prevalence studies focusing on adolescents [14, 25, 35] have used BEWE scores but with a cutoff value of 1 for DE diagnosis (Table 1). They reported prevalences higher than 50 %, as in our study, and an increase of the prevalence from 39 to 56.8 % by changing the cutoff value (Table 2). There is therefore a problem of both index choice and cut off value, not forgetting the type of tooth wear registered. Studies considering erosion, attrition (wear resulting from tooth to tooth grinding) and abrasion (wear resulting from tooth to other hard surfaces) showed higher prevalences [18, 22, 26, 27] compared with others (Table 1). This could be explained by an easier differential diagnosis in the young population than in the adult one [2, 24, 49]. Finally, the kind of tooth examined influenced the DE prevalence: the examination of maxillary incisors decreased significantly the DE prevalence whereas there was no significant difference between other situations (Table 2). Our results confirm those of other studies, since erosion was found to be greater in posterior than in anterior teeth and the most frequently affected teeth were the lower first molars [2, 3, 16, 17, 22, 31, 33] (Table 3). The most common clinical manifestation of DE was the appearance of cup-like lesions on the cusp tip of lower first molars. By contrast, other studies have recorded DE mainly on anterior teeth [4, 5, 9–11, 24, 28, 29] where loss of smooth surface enamel is more difficult to see [50]. Yet our examination conditions in schools were optimal due to adequate light and drying facilities. The absence of DE on mandibular incisors in Table 2 is due to their protection from acid attack by the high flow of submandibular saliva [5]. Thus the examination of upper incisors alone and first molars appears sufficient in prevalence studies carried out in adolescents at an age to be fixed by consensus. In the present study, the age of 14 years was used for examination of all teeth due to exposition to possible intrinsic and extrinsic aetiological factors for some time; if examining upper incisors and first molars can be considered sufficient, adolescents could be examined at the age of 12. This age should allow both DE prevalence and dental caries to be registered in the same study. Regarding severity, the first degree involving the enamel alone was most common, as has been reported in most of the studies in adolescents [4–7, 10–12, 19–21, 28, 30, 32, 34, 49]. To conclude this first part focusing on prevalence, the limitations of the present study should be

considered. The study sample was not nationally representative. As the majority of prevalence studies [4–8, 10–12, 16–31, 33–35] (Table 1), it was a stratified sample in a particular area fairly representative of the target population. Thus the application of the results to the French population needs to be confirmed.

Dental erosion is considered a multifactorial condition. Because the present study was cross-sectional and not longitudinal, the design only permitted an analysis of the association between known risk factors and experience of DE in French adolescents to highlight eventual particular cultural behaviors. As in previous studies [17, 24], no significant difference in the prevalence of DE between urban and rural areas was found in adjusted logistic regression analyses. Contrary to the majority of the studies [3, 5, 8–11, 16–18, 25, 28, 33, 34], socioeconomic status was associated with the experience of DE: the present study confirmed a significantly higher DE prevalence in the lowest social category [12, 24, 26, 32, 35, 49] more often cited than the contrary [7, 23]. The use of different indices could again explain these different results, because the significance of the

All consumers drank acidic beverages during and between meals: 94 % of them were sugared and the most consumed beverages were Cola (89 %) and Powerade (71 %). 1 (9.4 %) or 2 (90.3 %) daily tooth brushing. ICDAS 4–6 or ICDAS 1–6 carious lesions were included in the adjusted logistic regression analyses. *p > 0.1
association differed according the indices used in the same study [35]. Indeed socio-economic status had no effect on the dependant variable when a cutoff value of 1 was chosen (Table 5). Sex was not associated with DE prevalence, a result that is in accordance with numerous studies [4, 5, 7, 9–12, 17, 18, 25, 34, 35]. This may be explained by a similar pattern of exposure to risk factors in both sexes. A higher prevalence in males was found more particularly in studies which considered all tooth wear [22, 26, 30] and it was explained by differences in muscular strength and biting forces [26]. However, others studies targeting only DE found significant differences between the sexes [2, 3, 24, 28, 29, 31, 33] and one study showed a higher prevalence in girls [24].

Concerning oral health, the significantly greater occurrence of DE in the presence of carious lesions ICDAS 1–6 or 4–6 was inconsistent because the relationships were not statistically significant in adjusted logistic regression analyses (Table 4). This is in agreement with different studies using the DMFT (Decayed, Missing, Filled Teeth) index as independent variable [5, 11, 20, 31, 33]. However, caries experience was greater [25, 28] or lesser in adolescents with erosive experience [22] according to the studies. These different results could be explained by

consumption habits of acidic beverages, sugar-free (light) or regular soda drinks. In the present study, this tendency to proportional relationship between carious lesions and DE could be explained by a higher proportion of participants who consumed acid and sugar-containing cola beverages. The inconsistent relationship between DE and carious carious lesions can be explained by the inclusion of visible dental biofilm in one adjusted logistic regression analysis (Table 4). In all cases, the associations were close to statistical significance (Tables 4 and 5). Usually, dental biofilm protects enamel from erosive lesions, especially on anterior teeth. In contrast, the main consumption of both sugary and acidic beverages or sweets in the present study increased the quantity of dental plaque, which was significantly associated with higher DE prevalence. As in other studies [3, 12, 15, 16, 22, 24, 30], no statistically significant association was observed between oral behaviours (daily toothbrushing with fluoride toothpaste, dental examination during the past year) and DE. Only the study of Bardolia et al. [31] showed that a brushing twice a day increased the risk of DE.

Thus, diet plays a major role. In agreement with the majority of studies in adolescents since the 2000s, strong associations were found between DE and acidic beverages [6, 12, 15, 17, 20, 23–25, 30, 31] or sweets [17, 18, 23] (Table 4). However, the acidic beverage was the sole risk factor to have an effect on the DE, whatever the cutoff value of total BEWE score (Tables 4 and 5). In France, this could be due to a parent education problem about oral health because drinks and food dispensers have been prohibited in schools since 2005. The method of drinking, keeping or not the beverage in the mouth, was also associated with DE [13, 15–17, 30]. Only two studies did not show these associations [4, 11]. In the present study, the method of drinking had an effect on the DE for a cutoff value of 1. The frequent behaviour of children of retaining a drink in the mouth could be explained by a particular position of the tongue, the higher DE rates on second premolars compared with first premolars. While there are conflicting results from different studies, the present work confirms the most frequent results for sports drinks [6, 8, 9, 19, 24, 29], fresh fruits [6, 8, 9, 13, 24, 31] and daily vitamin C [9, 17] which were not associated with DE. Only one study (sports drinks; [15]) and four studies (fresh fruits; [17–19, 22]) showed contrary results; in the case of fresh fruits, this concerned only oranges [22], lemon [17] or banana [19]. The present study confirmed that acid reflux and repeated vomiting were not associated with DE in adolescents [9, 11, 14, 24, 29]. Only two studies, both using TWI modified indices (which over assess DE), reported the contrary [15, 16]. This setting can sometimes be difficult to evaluate due to its subjectivity.

Conclusion
The DE prevalence in Alpes Maritimes (France) was estimated to reach 39%. It is difficult to compare this estimate with other national prevalences due to the wide range of indices, choice of teeth and age used in different studies. Although the BEWE index has been recommended, the cut-off value of 1 still needs to be stipulated, for comparison with recent studies. The examination of maxillary incisors and first permanent molars appeared sufficient for assessing DE prevalence. Finally, the age of examination should be discussed because using 12-year-olds would have the advantage of allowing a prevalence study of both DE and caries prevalence.

Abbreviations
DE: Dental erosion; BEWE: Basic Erosive Wear Examination; AM: Alpes Maritimes; PES: Priority education schools; ICDAS: International Caries Detection and Assessment System; TWI: Tooth wear index; DMFT: Decayed: missing, filled teeth; OR: Odds ratio; 95% CI: 95% confidence interval.

Competing interests
This study was supported by a grant from the CG06 (Alpes Maritimes) and GABA International. The supporters played no role in data collection and analysis. The authors declare that they have no conflicts of interest.

Authors’ contributions
Some authors have made substantial contributions to conception and design of the study (LLP, MMB), acquisition (TB, MMB) analysis (LLP, MMB) and interpretation of data (FC, VSF, MMB); MMB has been involved in drafting the manuscript; FC and VSF have been involved in revising it critically for intellectual content. All authors read and approved the final manuscript.
