HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
We report and discuss analytical solutions of the vector nonlinear Schrödinger equation that describe rogue waves in the defocusing regime. This family of solutions includes bright-dark and dark-dark rogue waves. The link between modulational instability (MI) and rogue waves is displayed by showing that only a peculiar kind of MI, namely baseband MI, can sustain rogue-wave formation. The existence of vector rogue waves in the defocusing regime is expected to be a crucial progress in explaining extreme waves in a variety of physical scenarios described by multicomponent systems, from oceanography to optics and plasma physics.

Introduction.—Rogue waves are extremely violent phenomena in the ocean: an encounter with such a wave can be disastrous even to big ocean liners. These waves can also be very dangerous for various hydrotechnic constructions. This makes the study of rogue waves a very important problem. Hence, it is not surprising that the phenomenon of rogue waves has attracted ample attention of oceanographers in the last decade [1–4]. However, although the existence of rogue waves has now been confirmed by multiple observations, uncertainty remains on their fundamental origins. This hampers systematic approaches to study their characteristics, including the predictability of their appearance [5].

The research on rogue waves in oceans has attracted recently the attention of researchers in many other fields of physics [6]: optics [7], atmosphere [8], plasmas [9], and Bose-Einstein condensates [10].

The possibility to reach a general understanding of rogue-wave formation is still an open question [6]. Nonetheless, the ongoing debate stimulates the comparison of predictions and observations between distinct topical areas, in particular, hydrodynamics and nonlinear optics [11], in situations where analogous dynamical behaviors can be identified through the use of common mathematical models.

So far, the focusing nonlinear Schrödinger equation (NLSE) has played a pivotal role as a universal model for rogue-wave solutions. The Peregrine soliton, predicted 30 years ago [12], is the simplest rogue-wave solution associated with the focusing NLSE, and it has been recently experimentally observed in optical fibers [13], water-wave tanks [14], and plasmas [9].

While rogue-wave investigations are flourishing in several fields of science, moving beyond the standard focusing NLSE description in order to model more general and important classes of physical systems is both relevant and necessary. In this direction, recent developments consist in (i) including dissipative terms, since a substantial supply of energy (e.g., wind in oceanography) is generally required to drive rogue-wave formation [15], or in (ii) including higher-order perturbation terms such as in the Hirota equation and in the Sasa-Satsuma equation [16,17], because of the high amplitude or great steepness of a rogue wave, or in (iii) considering wave propagation in $2 + 1$ dimensions as for the Davey-Stewartson equation [18]. Additional important progress has been recently obtained by extending the search for rogue-wave solutions to coupled-wave systems, since numerous physical phenomena require modeling waves with two or more components in order to account for different modes, frequencies, or polarizations. When compared to scalar dynamical systems, vector systems may allow for energy transfer between their additional degrees of freedom, which potentially yields rich and significant new families of vector rogue-wave solutions. Indeed, rogue-wave families have been recently found as solutions of the focusing vector NLSE (VNLSE) [19–22], the three wave resonant interaction equations [23,24], the coupled Hirota equations [25], and the long-wave-short-wave resonance [26].

It is a well-established fact that, for the scalar NLSE, the focusing nonlinear regime is a prerequisite for the emergence of regular or random rogue waves (see, e.g., the discussion in [6]). To the contrary, in the scalar case the defocusing nonlinear regime does not allow for rogue-wave solutions, even of a dark nature. In coupled-wave systems, is the focusing regime still a prerequisite for the existence of rogue-wave solutions? Or it possible to find examples of rogue waves in defocusing regimes?

Additionally, what are the conditions under which modulation instability (MI) may produce an extreme wave...
event? Indeed, it is generally recognized that MI is among
the several mechanisms which generate rogue waves [12].
A rogue wave may be the result of MI, but not every kind of
MI leads to rogue-wave generation [27–29].

In this Letter, we prove the existence of rogue-wave
solutions of the VNLSE in the defocusing regime. We
evince that MI is a necessary but not a sufficient condition
for the existence of rogue waves. In fact, rogue
waves can exist if and only if the MI gain band also
contains the zero-frequency perturbation as a limiting case (baseband MI).

Defocusing VNLSE and rogue waves.—We consider the
VNLSE (also known as the Manakov system) which we
write in the following dimensionless form:

\begin{align}
  i \dot{E}^{(1)}(x,t) + E^{(1)}(x,t) - 2s(|E^{(1)}|^2 + |E^{(2)}|^2)E^{(1)} &= 0, \\
  i \dot{E}^{(2)}(x,t) + E^{(2)}(x,t) - 2s(|E^{(1)}|^2 + |E^{(2)}|^2)E^{(2)} &= 0,
\end{align}

where $E^{(1)}(x,t)$, $E^{(2)}(x,t)$ represent the wave envelopes
and $x, t$ are the transverse and longitudinal coordinates,
respectively. Each subscripted variable in Eq. (1) stands for
partial differentiation. It should be pointed out that the
meaning of the dependent variables $E^{(1)}(x,t)$, $E^{(2)}(x,t)$
and of the coordinates $x, t$ depends on the particular
applicable context (e.g., nonlinear optics, water waves,
plasma physics).

We have normalized Eq. (1) in a way such that $s = \pm 1$.
Note that in the case $s = -1$, Eq. (1) refers to the focusing
(or anomalous dispersion) regime; in the case $s = 1$,
Eq. (1) refers to the defocusing (or normal dispersion)
regime.

Like the scalar NLSE, the focusing VNLSE, Eq. (1), also
possesses rogue-wave solitons [19–22]. Unlike the scalar
case, and far from being obvious, we find that rational
solutions of the defocusing VNLSE do indeed exist, with
the property of representing amplitude peaks which are
localized in both $x$ and $t$ coordinates. These solutions are
constructed by means of the standard Darboux dressing
method [30,31] and, for Eq. (1) with $s = 1$, they can be
expressed as

\begin{equation}
  E^{(j)} = E_0^{(j)} \left[ \frac{p^2x^2 + p^4t^2 + px(\alpha_j + \beta \nu_j) - i\alpha_j p^2 t + \beta \nu_j}{p^2x^2 + p^4t^2 + \beta(px+1)} \right],
\end{equation}

where

\begin{equation}
  E_0^{(j)} = a_j e^{i(q_j x - \omega_j t)}, \quad \nu_j = q_j^2 + 2(a_1^2 + a_2^2), \quad j = 1, 2,
\end{equation}

represent the backgrounds of Eq. (2),

\begin{align}
  \alpha_j &= 4p^2/(p^2 + 4q_j^2), \\
  \theta_j &= (2q_j + ip)/(2q_j - ip), \quad j = 1, 2; \\
  \beta &= p^3/\chi(p^2 + 4q_1q_2), \quad p = 2\text{Im}(\lambda + k),
\end{align}

$q_1 + q_2 = 2\text{Re}(\lambda + k), \quad q_1 - q_2 = 2q, \quad \chi = \text{Im}k.$

As for the computation of the complex value of $\lambda$ and $k$
(see [24]), $\lambda$ is the double solution of the polynomial:

\begin{equation}
  \lambda^3 + A_2\lambda^2 + A_1\lambda + A_0 = 0,
\end{equation}

with

\begin{align}
  A_0 &= -k^3 + k(q_1^2 + a_1^2 + a_2^2) + q(a_2^2 - a_1^2); \\
  A_1 &= -k^3 - q_2^2 + a_1^2 + a_2^2; \\
  A_2 &= k.
\end{align}

The constraint on the double roots in Eq. (4) is satisfied
when the discriminant of Eq. (4) is zero, which results in
the fourth order polynomial condition:

\begin{equation}
  k^4 + D_3k^3 + D_2k^2 + D_1k + D_0 = 0,
\end{equation}

with

\begin{align}
  D_0 &= (q_1^2 - a_1^2 - a_2^2)^3/(24q^2) - (3/4)^3(a_1^2 - a_2^2)^2; \\
  D_1 &= -9(a_1^2 - a_2^2)(2q^2 + a_1^2 + a_2^2)/(24q^2); \\
  D_2 &= -[8q^4 - (a_1^2 + a_2^2)^2 + 20q^2(a_2^2 + a_2^2)]/(24q^2); \\
  D_3 &= (a_1^2 - a_2^2)/(2q).
\end{align}

Thus, $\lambda$ is the double solution of the third order polynomial,
Eq. (4), and $k$ is either one of the strictly complex solutions
of the fourth order polynomial, Eq. (5) [real solutions have
to be neglected to avoid singular solutions in Eq. (2)].

The expressions reported above depend on the real
parameters $a_1, a_2$ and $q$ which originate from the naked
solution, Eq. (3), namely, from the backgrounds: $a_1, a_2$
represent the amplitudes, and $2q$ represents the “frequency”
difference of the waves.

Figure 1 shows a typical dark-bright solution, Eq. (2),
while Fig. 2 shows a typical dark-dark solution, Eq. (2).
Eq. (5) has two real roots, to which no rogue wave is regime, threshold conditions for the parameters associated, and two complex conjugate wave existence condition:

\[ a \] in the (large amplitudes) subset background solution, Eq.(3), and then we prove that the computing the discriminant of Eq.(5). If this discriminant must be strictly complex, and that \( a_1, a_2 \) represent “amplitudes” (which, with no loss of generality, we take as real valued), and \( q_1, q_2 \) represent “frequencies.” A perturbed nonlinear background can be written as \( E^{(j)}_0 = [a_j + p_j]e^{i(q_j x - \omega_j t)} \), where \( p_j(x,t) \) are small perturbations (in amplitude and phase) which satisfy a linear equation. Whenever \( p_j(x,t) \) are \(-x\)-periodic with frequency \( Q \), i.e., \( p_j(x,t) = \eta_{j,s}(t)e^{iQx} + \eta_{j,a}(t)e^{-iQx} \), their equations reduce to the \( 4 \times 4 \) linear differential equation \( \eta' = iM\eta \), with \( \eta = [\eta_{1,s}, \eta_{1,a}, \eta_{2,s}, \eta_{2,a}]^T \) (here a prime stands for differentiation with respect to \( t \)). For any given real frequency \( Q \), the generic perturbation \( \eta(t) \) is a linear combination of exponentials \( \exp(i\omega jt) \) where \( \omega_j, j = 1, \ldots, 4 \), are the four eigenvalues of the matrix \( M \). Since the entries \( M_{mn} \) of the matrix \( M \) are all real, \( M_{11} = -Q^2 - 2Qq_1 - 2sa_1^2 \), \( M_{22} = -Q^2 - 2Qq_1 + 2sa_1^2 \), \( M_{33} = Q^2 - 2Qq_2 - 2sa_2^2 \), \( M_{44} = Q^2 - 2Qq_2 + 2sa_2^2 \), \( M_{12} = M_{13} = M_{23} = M_{24} = M_{34} = M_{43} = M_{42} = -2sa_1 a_2 \), the eigenvalues \( \omega_j \) are either real or come as complex conjugate pairs. They are the roots of the characteristic polynomial of the matrix \( M \),

\[
B(w) = w^4 + B_3 w^3 + B_2 w^2 + B_1 w + B_0,
\]

with

\[
B_0 = (Q^2 - 4q^2)[4(sa_1^2 + sa_2^2 - q^2)] + Q^2]Q^4;
\]

\[
B_1 = 16q(sa_1^2 - sa_2^2)Q^3;
\]

\[
B_2 = -2[2(sa_1^2 + sa_2^2 + 2q^2)] + Q^2]Q^2;
\]

\[
B_3 = 0.
\]

FIG. 2 (color online). Rogue waves envelope distributions \( |E^{(1)}(x,t)| \) and \( |E^{(2)}(x,t)| \) of Eq. (2). Here, \( a_1 = 3, a_2 = 3, q = 1. \ k = 4.02518i \) and \( \lambda = -4.92887i \).

The family of solutions, Eq. (2), found in the defocusing regime, possesses a novel feature with respect to families of the solutions of Eq. (1) previously reported in focusing regimes (see, e.g., [20–22]). In fact, in the defocusing regime, threshold conditions for the parameters \( a_1, a_2, q \) exist due to the requirement that the solution \( k \) of Eq. (5) must be strictly complex, and that \( \lambda \) is a double solution of Eq. (4). We have identified these threshold conditions by computing the discriminant of Eq. (5). If this discriminant is positive, Eq. (5) possesses four real \( k \) roots, and rogue waves do not exist, while if the discriminant is negative, Eq. (5) has two real roots, to which no rogue wave is associated, and two complex conjugate \( k \) roots, which instead imply the existence of rogue waves. This constraint on the sign of the discriminant leads to the following rogue-wave existence condition:

\[
(a_1^2 + a_2^2)^3 - 12(a_1^4 - 7a_1^2a_2^2 + a_2^4)q^2 + 48(a_1^2 + a_2^2)q^4 - 64q^6 > 0.
\]

Figures 3(a) and 3(b) report two characteristic examples of rogue-wave existence conditions. In particular, Fig. 3(b) shows that, for fixed \( q \), the background amplitudes have to be sufficiently large to allow for rogue-wave formation. As a particularly simple example, consider the case \( a_1 = a_2 = a \) and \( q \neq 0 \). In this case, the inequality, Eq. (6), reads \( 4(a^2 + 4q^2)^2(2a^2 - q^2) > 0 \), with the implication that only in the (large amplitudes) subset \( a^2 > q^2/2 \) of the parameter plane \( (a, q) \) do the rogue waves, Eq. (2), exist.

Defocusing VNLS and induced MI.—Here we first turn our attention to the standard linear stability analysis of the background solution, Eq. (3), and then we prove that the existence of rogue waves is strictly related with a specific form of MI, namely, to baseband MI. In the following, the coupling parameter \( s \) in Eq. (1) is considered as a continuous variable rather than a discrete, two-valued variable (i.e., \( s = \pm 1 \)). Therefore, the background solution takes the expression \( E_0^{(j)} = a_j e^{i(q_j x - \omega_j t)} \), with \( \nu_j = q_j^2 + 2(a_1^2 + a_2^2)j = 1, 2 \), while \( a_1, a_2 \) represent “amplitudes” (which, with no loss of generality, we take as real valued), and \( q_1, q_2 \) represent “frequencies.” A perturbed nonlinear background can be written as \( E_0^{(j)} = [a_j + p_j]e^{i(q_j x - \omega_j t)} \), where \( p_j(x,t) \) are small perturbations (in amplitude and phase) which satisfy a linear equation. Whenever \( p_j(x,t) \) are \(-x\)-periodic with frequency \( Q \), i.e., \( p_j(x,t) = \eta_{j,s}(t)e^{iQx} + \eta_{j,a}(t)e^{-iQx} \), their equations reduce to the \( 4 \times 4 \) linear differential equation \( \eta' = iM\eta \), with \( \eta = [\eta_{1,s}, \eta_{1,a}, \eta_{2,s}, \eta_{2,a}]^T \) (here a prime stands for differentiation with respect to \( t \)). For any given real frequency \( Q \), the generic perturbation \( \eta(t) \) is a linear combination of exponentials \( \exp(i\omega jt) \) where \( \omega_j, j = 1, \ldots, 4 \), are the four eigenvalues of the matrix \( M \). Since the entries \( M_{mn} \) of the matrix \( M \) are all real, \( M_{11} = -Q^2 - 2Qq_1 - 2sa_1^2 \), \( M_{22} = -Q^2 - 2Qq_1 + 2sa_1^2 \), \( M_{33} = Q^2 - 2Qq_2 - 2sa_2^2 \), \( M_{44} = Q^2 - 2Qq_2 + 2sa_2^2 \), \( M_{12} = M_{13} = M_{23} = M_{24} = M_{34} = M_{43} = M_{42} = -2sa_1 a_2 \), the eigenvalues \( \omega_j \) are either real or come as complex conjugate pairs. They are the roots of the characteristic polynomial of the matrix \( M \),

\[
B(w) = w^4 + B_3 w^3 + B_2 w^2 + B_1 w + B_0,
\]

with

\[
B_0 = (Q^2 - 4q^2)[4(sa_1^2 + sa_2^2 - q^2)] + Q^2]Q^4;
\]

\[
B_1 = 16q(sa_1^2 - sa_2^2)Q^3;
\]

\[
B_2 = -2[2(sa_1^2 + sa_2^2 + 2q^2)] + Q^2]Q^2;
\]

\[
B_3 = 0.
\]

FIG. 3 (color online). Rogue-wave existence condition, Eq. (6). (a) \((q, a_1)\) plane, with \( a_2 = 3 \). (b) \((a_2, a_1)\) plane, with \( q = 4 \).
We remark that no rogue waves exist in this defocusing regime.

Figure 4(b) corresponds to the case where the nonlinear background modes have opposite frequencies \((q_1 = - q_2 = q)\), in a defocusing regime \(s = 1\) which yields MI. The higher that \(q\) is, the higher that \(G\) becomes. In the special case of equal background amplitudes \(a_1 = a_2 = a\), the marginal stability condition \(Q^2 = 4q^2\) can be found analytically: \(Q^2 = \max\{4q^2 - 8a^2, 0\}\). Thus, for \(a^2 > q^2/2\), a baseband or low pass MI, which includes frequencies that are arbitrarily close to zero, is present (i.e., \(0 < Q^2 < 4q^2\)). Instead, for \(a^2 \leq q^2/2\), the MI occurs for frequencies in the passband range \(4q^2 - 8a^2 < Q^2 < 4q^2\). We remark that in the previous section we have shown that rogue waves, Eq. (2), necessarily exist for \(a^2 > q^2/2\) [e.g., the parameters of the rogue wave of Fig. 2 correspond to the baseband MI as shown in Fig. 4(b)]. Thus, rogue waves, Eq. (2), and baseband MI coexist.

Figure 4(c) corresponds to the case in which the nonlinear background modes have different frequencies \((q_1 = - q_2 = q)\), and different input amplitudes \(a_1 \neq a_2\) in the defocusing regime \(s = 1\). For low values of \(a_1\), only passband MI is present. By increasing \(a_1\), the baseband MI condition is eventually reached.

Thus, we proceed by focusing our interest on the MI behavior in the limit \(Q \to 0\), namely, on the occurrence of baseband MI. To this aim, we rewrite the characteristic polynomial (7) as \(B(Q) = Q^2b(v)\) and consider the polynomial \(b(v)\) at \(Q = 0\), namely,

\[
b(v) = v^4 + b_3v^3 + b_2v^2 + b_1v + b_0,
\]

with

\[
b_0 = -16q^2(a_1^2 + a_2^2 - q^2);
\]

\[
b_1 = 16q(a_1^2 - a_2^2);
\]

\[
b_2 = -4(a_1^2 + a_2^2 + 2q^2);
\]

\[
b_3 = 0.
\]

Next, we have evaluated the discriminant of Eq. (8). If the discriminant is positive, the polynomial, Eq. (8), possesses four real roots, and no MI occurs, while if the discriminant is negative, Eq. (8) possesses two real roots and two complex conjugate roots, and Eq. (1) exhibits baseband MI.

The interesting finding is that the previous sign constraint on the discriminant of the polynomial, Eq. (8), which leads to the baseband MI condition, turns out to coincide with the sign constraint, Eq. (6), which is required for rogue-wave existence.

These results are important as they show that (i) the rogue-wave solutions, Eq. (2), exist in defocusing regimes in the subset of the parameter space where MI is present, and (ii) the rogue-waves solutions, Eq. (2), exist if and only if baseband MI is present.

The link between baseband MI and rogue waves can be understood if we consider that these rogue waves are rational solutions; thus, when \(t \to -\infty\), they approach the constant background plus weak long-term waves. The fact that these weak long waves eventually rise to a finite amplitude is basically equivalent to baseband instability. Our contribution has been that of substantiating this qualitative argument by precisely formulating the explicit condition for the existence of both the baseband MI and the rogue waves.

We verified the outcome of our theoretical analysis by numerically solving the VNLSE in a wide range of parameters. We found that in the baseband MI regime, multiple rogue waves are generated from noise on top of an unstable plane wave background. Whereas, in the case of passband MI, we observed the birth of nonlinear oscillations with a period corresponding to the peak gain MI frequency. Examples of nonlinear time evolutions are shown in the Supplemental Material [36].
Conclusions.—We presented and analyzed exact, explicit rogue-wave solutions of the defocusing VNLS E. This family of solutions includes both bright and dark components. Moreover, we clarified that the rogue-wave existence condition is strictly related to a very specific manifestation of MI, namely, MI whose bandwidth includes arbitrarily small frequencies.

Because of the widespread fundamental and applicative interest of the VNLS E in the defocusing regime (in hydrodynamics, it applies to the shallow water regime; in nonlinear optics it describes nonlinear materials with normal group velocity dispersion, or diffraction in materials with a negative nonlinearity), we believe that our extreme wave solutions may have a significant impact in a variety of physical situations.

[30] The computation of rogue-wave solutions is based on the Darboux technique applied to the Lax pair associated with the VNLS E. This method is well known and does not need to be detailed here to any extent. The relevant literature is rather vast and we refer to [31] for the formalism and general set up adopted here, and to Refs. [20,24] (and to the literature quoted therein) for the basic arguments to follow for the construction of rational solutions.
