Optical microscopy analyses using thin sections is one of the most standard techniques in geology. It permits identification of most rock-forming minerals and it is essential for micropaleontology since observation in transmitted light is the only way to observe individual, or colonies of, microfossils in their mineralogical and textural context. Thin sections are also used for other techniques such as Raman spectroscopy. In the framework of exploration of the Martian surface and of the search for potential relics of microbial life, the possibility to observe petrographic thin sections *in situ* would be revolutionary. Nevertheless, although optical microscopes can be readily designed for space exploration, thin section preparation is not easy to do *in situ* on extraterrestrial rocky bodies due to the generally harsh environmental conditions and to the difficulty to automate a protocol that normally requires several human interventions. The aim of the LithoSpace project, supported by the French Space Agency (CNES) since 2014, is to work on the development of an automated system permitting preparation of petrographic thin sections on extraterrestrial bodies, such as Mars, the Moon or asteroids. In this paper, we describe the approaches used to study rocks *in situ* during space missions and compare them to those used on Earth. Then, the relevance of making thin sections during space exploration is highlighted from the description of the data that could be collected from the analysis of these specific samples, using new instruments and instruments already sent to Mars. The standard preparation protocol is described as well as previously envisioned or existing *in situ* sample preparation systems. We then propose a protocol for automation of the preparation. Particular attention is paid to demonstrating the feasibility of making thin sections in the absence of liquid water and with energy consumption compatible with automated space probes. Tests are then carried out to control the quality of the prepared samples. On the basis of the demonstrated feasibility, an automated system is proposed as a conceptual all-in-one system. Finally, a “proof-of-concept” model developed with the help of students at different educational levels is presented.

**Keywords:** thin section, optical microscopy, petrography, micropaleontology, Raman spectroscopy, Mars
INTRODUCTION

Studying Rocks on Extraterrestrial Bodies

Better exploration of the solar system necessitates sending space probes directly to the surface of rocky bodies (planets, satellites, and asteroids) since in situ analysis allows information to be obtained that is otherwise impossible to acquire. The principal domains concerned by these automated missions include atmospheric sciences, geology and astrobiology. Except for atmospheric studies, the principal materials of interest are solid materials (rocks and ices), whether for mineralogical studies, analysis of the organic molecules they contain, or for searching for putative traces of extant or extinct life. Analysis of rocks greatly aids understanding of the geological history of the explored body, from its internal (volcanism, tectonic, etc.) to surface processes (alteration, weathering, and sedimentology, etc.). This information is crucial in order to determine the habitability of the body and to evaluate if life may have appeared on it.

On Earth, the standard approach for the study of rocks comprises:

1. Studying the geological maps and the topography data of the explored area (if they exist) in order to evaluate the geological context.
2. Once in the field, to make observations (photograph and schematics) at various scales of landscapes and outcrops.
3. To make centimetre to sub-millimetre scale observations, eventually using a magnifying glass, in order to choose the most relevant hand samples for collection.
4. Once back at the laboratory, to carry out petrographic study of the collected samples. This step consists in identifying the minerals, studying the texture and structure of the rock, and detecting potential (micro-)fossils or microbial activity (petrology of carbonaceous matter, minerals and specific structures). This precise petrographic and (micro-) palaeontological study is made in optical microscopy using petrographic thin sections.
5. Finally, to make more specific and advanced analyses if needed (Raman spectroscopy, electron microprobe, X-ray diffraction, electron microscopy, in situ PIXE or LA-ICP-MS, etc.) in order to confirm the mineralogy, to identify minor phases, to analyse the organic matter content, to observe sub-micrometric fossils, for dating, or isotopic analysis etc. Some of the methods are improved by the use of thin sections and most of them are carried out in the light of the observations previously made by optical microscopy.

In the absence of a thin section preparation device during automated in situ space missions, the scientific exploration approach previously described is shortened on extraterrestrial bodies (the third step is skipped). Generally, sample preparation is relatively limited during space missions. For example, NASA’s Mars Exploration Rovers Spirit and Opportunity were "simply" equipped with a Rock Abrasion Tool to strip the surface of the rocks (Squyres et al., 2004; Thomson et al., 2014). The Curiosity rover of the Mars Science Laboratory NASA’s mission collects powdered rocks by drilling 50 mm below the surface (drill diameter 1.6 cm) (Grotzinger et al., 2012). The Perseverance rover of the NASA Mars 2020 mission is, meanwhile, capable of taking small drill cores from the surface (6 cm long and 1.3 cm diameter) to be returned to Earth in 2031 for further analyses (Farley et al., 2020). Finally, the ESA/Roscosmos ExoMars 2022 rover Rosalind Franklin is equipped with a drill capable of reaching a depth of 2 m and of sampling small cores (3 cm long and 1 cm diameter); however, these latter samples will be crushed prior to analysis inside the rover (Vago et al., 2017). While grinding the sample facilitates automation of the analyses, it is also highly detrimental for the comprehension of the rock since study of the texture and the structure is not possible, i.e., the link between the minerals, their size and their shape, which is essential for the interpretation of the rock. Obviously sample crushing inevitably leads to the destruction of the potential (micro-)fossils and biostructures (e.g., stromatolitic laminations) the rock may contain.

On the Interest of Thin Sections for Space Exploration

Thin sections are useful for many analysing methods. Hereafter is a non-exhaustive list:

Optical Microscopy

Thin sections are mostly made in order to carry out optical microscopy in transmitted light. This method is used to characterize the microstructure of rocks (texture, minerals, and fossils, etc.) since the 19th century. The first thin sections were prepared by William Nicol in 1815. Observation in transmitted and reflected light, plane polarized and crossed polarized light, permits identification of most rock-forming minerals and the detection of microfossils (see Figure 1) and other structures of interest such as fluid inclusions. Identification of minerals in cross-polarized transmitted light is based on their colour which depends on section thickness according to the Auguste Michel-Lévy colour chart, hence a standard thickness of 30 µm (Michel-Lévy and Lacroix, 1888). Finally, optical microscopy is commonly used for reconnaissance prior any other analyses.

Raman Spectroscopy

Raman spectroscopy is a vibrational spectroscopy using a laser to identify and characterize atomic bonds. It is particularly suited for astrobiology since it permits the detection of both organic and inorganic biosignatures (e.g., kerogen, pigments, and biominerals, etc.) (Jehlicka et al., 2009; Marshall et al., 2010; Vandenabeele et al., 2012; Vitek et al., 2012; Bower et al., 2013; Edwards et al., 2013; Foucher and Westall, 2013; Campbell et al., 2015; Baqué et al., 2016; Jehlička et al., 2016; Foucher, 2019). In the laboratory, Raman spectroscopy is generally interfaced with an optical microscope permitting localisation of areas of interest and to carry out analyses at the micrometre scale. On the other hand, remote Raman and/or field
systems, including the NASA Mars 2020 SHERLOC and SuperCam systems and the ESA/Roscosmos ExoMars 2022 Raman Laser Spectrometer, have a large spot size of several tens or hundreds of microns (Rull et al., 2017; Wiens et al., 2017). The spectra obtained correspond then to a mix of the spectra associated to the different components of the rock. This is particularly problematic when a phase is fluorescent because it generally masks the Raman signal of all the other phases. It has also been shown that the analysis of powdered samples can alter the spectroscopic signal (Foucher et al., 2013). Finally, the loss of texture associated with crushing means that Raman mapping cannot be used, despite the fact that they are particularly useful for the identification of microfossils (Foucher and Westall, 2013; Foucher et al., 2015; Bower et al., 2016, p. 16; Foucher, 2019). The development of a Raman micro-imager for planetary exploration is technically feasible since optical and scanning systems compatible with space environment already exist (Lopez-Reyes et al., 2013; Rull et al., 2017).

**Laser Induced Breakdown Spectroscopy**

This method uses a laser to create a plasma from the target sample and the emitted light is analysed by optical spectroscopy to determine its elemental composition. LIBS is already used on Mars during the NASA MSL and Mars 2020 missions with the ChemCam (Cousin et al., 2012; Grotzinger, 2013) and SuperCam (Wiens et al., 2017) instruments, respectively. In the laboratory, LIBS can be interfaced with optical microscopes to make analysis at the micrometre scale and to carry out elemental imaging (Fabre et al., 2018). It has also been shown that this method can be used to make isotopic dating by analysing specific minerals (Devismes et al., 2016). The possibility to make thin sections during planetary exploration would permit such analysis *in situ.*

**Cathodoluminescence**

This method uses an electron beam to induce the luminescence of a material. It is used in geosciences to detect trace elements and to understand the formation processes of minerals and rocks (e.g., Rusk et al., 2008). It has been shown to be relevant and compatible with space exploration (Thomas et al., 2009; Bost et al., 2013).

**Fluid inclusion analysis**

Fluid inclusions are small bubbles of gases or liquids trapped in minerals during their formation. Their analysis gives information on the environmental conditions (T, P, gases and liquids composition, salinity, etc.) existing when the rock formed. Such data would be particularly relevant to document the habitability of Mars by the past (Hode et al., 2003).
inclusions on Earth also contain microbial remains and/or well preserved organic molecules (Müßbach et al., 2021) and are, therefore, particularly interesting for astrobiology.

**Ice Analysis**
Thin sections are commonly used to study the crystallinity of ices on Earth (e.g., Montagnat et al., 2010). Such observations would be relevant during the exploration of Mars as well as of the Jupiter’s and Saturn’s icy satellites.

**Standard Protocol for Thin Section Preparation**
The standard and inescapable steps for making a thin section are as follows:

1. A piece of rock is taken from the hand sample and indurated in epoxy resin, preferentially under vacuum in order to facilitate the penetration of the resin. Marks are made in order to maintain the orientation of the sample.
2. A slab is cut from the indurated piece of rock in order to have at least one flat surface.
3. The flat surface of the slab is glued onto a frosted glass slide generally using the same resin as previously used for induration.
4. The glued slab is cut parallel to the glass slide in order to keep a 50–200 μm thick slice of rock glued onto the glass slide.
5. The slice of rock is thinned down to 30–35 μm by grinding. This step permits control of the parallelism of the two faces of the slice.
6. The thin section is lapped to a final thickness of 30 μm and its surface is polished.

The cutting steps can be done using a circular diamond saw or a wire saw. The grinding is carried out using circular grinder and the polishing is made with abrasive discs of various grain sizes. These cutting, grinding and polishing steps are generally made using water in order to remove the dust, facilitate the mechanical cutting and grinding, and to cool the material and the sample. The induration phase is crucial since it gives competency to the sample and prevents cracking or breaking during the different steps.

**Thin Section Preparation Device for Space Exploration**
Due to its high relevance, a thin section preparation device was envisioned relatively early in the history of space exploration. Thus, in the 1965, even if it was not used, a semi-automated system to be used by the astronauts named Petralab was developed for the Apollo Applications Program and Advanced Lunar Programs at USGS, Flagstaff, by Paul Cary from the NASA Astrogeology department (Dreyer et al., 2013b).

Since the Apollo missions, all the other exploration missions of extraterrestrial bodies were robotic. The preparation of thin section should thus be envisioned in a fully-automated way and not necessarily using standard environmental conditions. However, the pressure and temperature at the surface of extraterrestrial bodies in the solar system are not compatible with the use of liquid water and may compromise the use of resins. Considering these difficulties, a fully-automated preparation of simply polished sections (which does not permit observation in transmitted light) was envisioned by ESA in the framework of the Multi-User Facility for Exobiology Research project (Battistelli, 2000). In this study, the starting sample was a drill core that was successively ground and polished in order to facilitate the optical (reflected light), Atomic Force Microscopy (AFM) and Raman spectroscopy observations, prior to being crushed for APXS and Mössbauer analyses. Also, in the pre-project of the ExoMars mission, the Sample Preparation Subsystem was initially able to polish the drill cores and to incorporate powdered rocks into resin for Mössbauer analyses (Schulte, 2000). While it was demonstrated that cutting and polishing were feasible, the scientific interest of the observations in reflected light was considered too low and the system was finally abandoned. Research on the induration phase was not undertaken for similar reasons.

Recently, Dreyer et al. (2013a), Dreyer et al. (2013b) proposed and tested a prototype of automated thin section preparation device for space exploration called IS-ARTS for in situ Automated Rock Thin Section Instrument (Paulsen et al., 2013). This system permits making thin sections from centimetric samples of any shape. The sample is handled using an innovative system called “Rock Gripper” consisting of an array of spring loaded pins permitting adaptation to any sample shape. The sample is moved linearly and is successively cut, glued onto a glass slide, cut again and observed. The sample is cut using a wire saw and the sample is glued with wax. The induration of the sample is only envisioned for further developments. This promising system, thus, demonstrates the feasibility of making thin sections on extraterrestrial bodies.

More broadly, a compact all-in-one thin section preparation system is interesting for scientific field exploration on Earth. Goren (2014), for example, proposed a non-automated portable thin section preparation laboratory. Even though this system requires human intervention, it demonstrates the feasibility of making thin sections with a limited amount of material and using small batteries.

Here, we present the LithoSpace project, begun in 2012 and supported by the CNES since 2014 by their Research and Technology program, which adapts the standard laboratory thin section preparation protocol to automated planetary exploration. Based on a different approach, it proposes an alternative system to that envisioned by Dreyer et al. (2013a), Dreyer et al. (2013b) and by Goren (2014). The specifications of these devices are compared to those expected for the LithoSpace system in Table 1. The size, mass and average power were estimated based on the specifications of the ExoMars 2022 rover (analytical laboratory dimensions ~ 140 × 130 × 50 cm, mass = 310 kg, maximum drill power 70 W). Among the differences with other systems, we propose to use a disc saw rather than a wire saw since, by experience, a disc saw is more reliable and the surface finish after cutting is generally better. The
samples are also systematically indurated. For astrobiological purposes, the most interesting rocks to study are sedimentary rocks which may be particularly fragile and brittle except when indurated by a cement. Indeed, this is the situation of the sediments in Gale Crater on Mars. In order to validate these choices, we carried out energy consumption experiments and tested the feasibility of cutting indurated samples in the absence of liquid water. Finally, we propose a dimensionally optimized device making 30 µm thick thin sections from drill cores in a fully-automated way. While no functional prototype has been developed yet, several technical solutions are proposed and a model serving as a “proof-of-concept” was made based on the specifications of our system. Interestingly, we took the opportunity to use this project to make students aware of space exploration. Thus, fifth year students at the engineering school Polytech’ Orléans, University of Orléans, France, and students in BTS (2-year technical degree) course “Industrialisation of Mechanic Products” and in Licence Pro “Technical Coordinator of Industrialization Methods” from the Benjamin Franklin high school of Orléans, France, participated in the development of the system using Computer Aided Designed and in making a demonstration model.

**MATERIALS AND METHODS**

**Envisioned Protocol**

We considered that thin sections will be prepared from 2.5 cm long and 1 cm diameter cylinders, similar to the ExoMars drill cores (Vago et al., 2017) and comparable in diameter to the drill cores taken by the Perseverance Mars 2020 rover (Farley et al., 2020). The envisioned protocol is described in Figure 2. We considered that the cores are pushed out of the drill into a sample receiving drawer that emerges from the interior of the rover, similar to the Core Sample Transport Mechanism (CSTM) of the Sample Preparation and Distribution System (SPDS) of the ExoMars mission (Vago et al., 2017). Photographs of the drill cores are made using the cameras located outside the rover. In our study, these images would be used to know the sample orientation. The drawer is then moved back into the rover. During the ExoMars mission the collected drill core is subsequently crushed while in our study it could be placed in an induration tank. In order to validate the feasibility of this protocol in the absence of water, cutting tests were undertaken using different types of rock. The power required to cut the rocks and their final surface finish were studied.

| System | LithoSpace (this study) | IS-ARTS (Dreyer et al., 2013a) | Goren (2014) |
|---|---|---|---|
| Automation | Fully automated | Fully automated | Semi-automated |
| Initial sample | Drill core | Hand sample | Hand sample |
| Induration | Yes | No | Optional |
| Cutting device | Disk saw | Wire saw | Disk saw |
| Water | No | No | Yes |
| Power | 50 W (max) | 23 W | ~25 W |
| Dimensions | 40 × 40 × 50 cm (max) | Not provided | 55 × 40 × 20 cm (disassembled) |
| Mass | 15 kg (max) | 14.4 kg | 10 kg |
| Number of sections | 30 | >50 | Not limited |
| Sample size | 20 × 30 mm | 20 × 20 mm | Up to 50 × 75 mm |

**FIGURE 2** | Schematic protocol for automated thin section preparation. (A–C) A drill core is placed into a container and indurated. (C,D) The whole is cut in the middle along the core axis. (E,F) A layer of resin is deposited and a glass slide is glued on the top of the remaining sample. (G) The sample is cut close to the glass slide in order to keep a ~100 µm thick slice of rock. (H,I) The rock surface is ground and polished. (J) The 30 µm rock thin section is analysed from the bottom with an inverted microscope.
**Rock Samples**

The proposed protocol was tested using a series of rocks of various compositions and physical properties. Most of these samples come from the *International Space Analogue Rockstore* (ISAR), http://isar.crns-orleans.fr, (Bost et al., 2013).

*Basalt.* Basalt from the Massif Central was chosen for its high relevance for Mars (ISAR reference 14FR08).

*Komatiite.* Komatiites are very primitive ultramafic rocks considered as good analogue for Mars (Bost et al., 2015). The sample comes from South Africa (ISAR reference 10ZA09).

*Chert.* Chert was chosen for its very low hardness and for its tendency to form sticky powder/paste during sawing and grinding.

*Chalk.* Chalk was chosen for its low hardness and for its practical reasons related to the sample scale of mineral hardness.

**Sample Preparation Instruments**

Two disc saws were used at CEMHTI, CNRS, Orléans, France, for cutting tests.

*Disc saw Presi P100.* This simple system uses a variable speed electric engine to drive the disc. The sample is fixed on the top of the saw and the applied force is set using different weights. The cutting is thus carried out at constant load. For the tests, an ESCIL NC100 disc, 100 mm diameter, 0.3 mm thick was used and small brushes were added at the bottom of saw to remove dust in the absence of water.

*Disc saw Struers Secotom-10.* This precise cutting device is equipped with two variable speed electric engines, one to drive the disc and one to move the sample. Contrary to the Presi P100 device, cutting is made at constant sample displacement speed. The load, i.e., the force applied by the sample onto the saw, was measured during the cutting. Tests were carried out using an ESCIL R100-5 disc, 100 mm diameter, 0.4 mm thick and small brushes were added at the bottom of the saw to remove dust from the disc in the absence of water.

These systems were plugged into a power meter in order to evaluate their power consumption. It is important to note that this power corresponds to the maximal power used, not to the power really delivered by the engines, since the power meter does not take into account the phase shift existing between the intensity and the voltage associated with AC engines and since a part of the power is used for the electronics.

**Analysis Devices**

All the analyses were made at CBM, CNRS, and Orléans.

Optical microscopy observations were carried out using an Olympus BX 51 microscope, both in transmitted and reflected light.

Surface roughness was estimated by Atomic Force Microscopy (AFM) using a Veeco Dimension 3,100 system in contact mode (Budget Sensors Cont-Al tips). The surface of the samples was scanned perpendicularly to the cutting streaks. Data processing was made using the WSxM software (Horcas et al., 2007).

Raman spectroscopy was used to characterize the sample. All the experiments were carried out using a WITec Alpha 500RA system equipped with a green laser (Nd:YAG frequency doubled laser) of wavelength $\lambda = 532$ nm. Raman imaging, obtained by 2D scanning of the sample surface, was used to document the mineralogy. For this study, a $\times$ 20 Nikon E Plan (numerical aperture N.A. = 0.40) objective was used. Raman spectra were acquired using a 600 g/mm grating spectrometer ranging from approximately $-150$ to $3,800$ cm$^{-1}$ and a resolution ranging from 3 to $5$ cm$^{-1}$. Laser power at the sample surface was set to 13 mW. Detailed information on micro-Raman imaging can be found in Foucher et al. (2017).

**RESULTS**

**Power Consumption**

*Presi P100 Disc saw.*

The power consumption of the system with the engine off is 6 W. At maximum disc rotation speed, the system consumes 46 W (i.e., without sample). The return to zero is not associated with a return to standby consumption but with a basic consumption of $\sim 20$ W due to the phase shift not taken into account by the power meter.

The first cutting test was performed on the chalk sample. For practical reasons related to the sample fixation system, cutting was carried out parallel to the longitudinal axis of the chalk (see Figure 3). For the load, a mass of 185.5 g was chosen for the test, more or less arbitrarily. Figure 3 shows the evolution of electricity consumption over time.

It is shown that the power consumption increases slowly during the first 15 min and then increases regularly over time to reach 129 W after 55 min. Cutting was then stopped because the machine became very hot. Thus, part of the increase in consumption can be attributed to Joule heating. After a break of 30 min, cutting resumed but was stopped immediately because the blade broke. By this time more than 80% of the sample had been cut.

*Struers Secotom-10 Disc saw.*

The power consumption of the system with all engines off is 10 W. When cutting, it is impossible to stop the water pump which consumes 35 W. With the electronics, the system therefore consumes 45 W with the engines off. Switching on followed by a return to zero did not make any difference in power consumption on this system. The variation in consumption of the motor allowing the movement of the sample varies little with the sample displacement speed $v_d$. The difference in consumption between the maximum ($v_d = 3$ mm s$^{-1}$) and minimum ($v_d = 0.005$ mm s$^{-1}$) speed is only 5 W. In order to determine the power consumption of the system with respect to the disc rotation speed $v_r$, tests were carried out without a sample with a speed $v_d = 0.005$ mm s$^{-1}$. In the studied range (300–1,500 rpm), the power consumption $P$ increases linearly with the speed of $v_r$. The 3.45 billion year old Kitty laser) of wavelength $\lambda$.

The 3.45 billion year old Kitty laser) of wavelength $\lambda$.

The 3.45 billion year old Kitty laser) of wavelength $\lambda$.
FIGURE 3 | Evolution of power consumption over time during the cutting of a chalk sample (in insert) using the Presi P100 disc saw.

FIGURE 4 | (A) Power consumption of the Struers Secotom 10 disc saw versus disc rotation speed. (B–D) Power consumption versus time for various samples and parameters: (B) chert sample, water on, $v_d = 900$ rpm and $v_s = 0.095$ mm $s^{-1}$ (in blue), and $v_d = 900$ rpm and $v_s = 0.05$ mm $s^{-1}$ (in red), (C) komatite sample, water off, $v_d = 900$ rpm and $v_s = 0.05$ mm $s^{-1}$, (D) basalt sample, water off, $v_d = 300$ rpm and $v_s = 0.01$ mm $s^{-1}$.
rotation of the disc according to the equation \( p = 0.025 \nu_d + 119.71 \) (see Figure 4A). The system allows samples to be cut through the section so the blade only cuts 1 cm of sample at the same time.

**Chert Sample**
A first chert sample was cut with water using a disc rotation speed \( \nu_d = 900 \text{ rpm} \) and a sample displacement speed \( \nu_s = 0.095 \text{ mm s}^{-1} \). The consumption before cutting was 150 W. Figure 4B shows the changes in power consumption over time. The cutting time was 8 min. It was observed that the electrical consumption increases rapidly with a peak at 213 W. This increase in consumption results in a significant increase of the load on the control panel. Once the sample was cut, the consumption fell back to its initial value (i.e. 150 W). A second sample was cut with a sample displacement speed that was twice as low \( \nu_s = 0.05 \text{ mm s}^{-1} \). The consumption before cutting was 147 W. The cutting time of the sample was logically double, i.e., 16 min (see Figure 4B).

Nevertheless, it was shown that the power consumption increases slowly and reaches a maximum of 173 W at the very end of the cutting. The increase of the load on the control panel remains small. Once the sample was cut, the consumption fell back to its initial value (i.e., 147 W).

**Komatiite Sample**
The komatiite sample was cut without using water with a disc rotation speed \( \nu_d = 900 \text{ rpm} \) and a sample displacement speed \( \nu_s = 0.05 \text{ mm s}^{-1} \). The consumption before cutting was 148 W. Figure 4C shows the changes in power consumption over time. In order to check disc heating, the system was stopped after 3 min; there was only a relatively limited increase in temperature. After this check, the blade was slightly retracted before resuming cutting. It then took 2 min before cutting actually resumed. The cutting test finally lasted 18 min (3 min + 2 min +13 min) including 16 min of actual cutting. The load increase on the control panel remained small throughout cutting. The electricity consumption increased gradually and reached its maximum of 202 W at the end of cutting. Once the sample was cut, the consumption fell back to its initial value (i.e., 148 W).

**Basalt Sample**
The basalt sample was cut without water. The system was set with the slowest possible disc rotation speed, \( \nu_d = 300 \text{ rpm} \), and a sample displacement speed \( \nu_s = 0.01 \text{ mm s}^{-1} \). Figure 4D shows the changes in power consumption over time. The consumption before cutting was 122 W. Cutting the sample took 87 min. The load increase on the control panel remained small throughout cutting. The power consumption gradually increased and reached a maximum of 172 W after 72 min. A plateau was then observed at about 152 W from the 72nd minute and at the end of the cut. This corresponds to a part of the sample only composed of resin. Finally, once the sample had been completely cut, power consumption was slightly higher, 127 versus 122 W. This difference is attributable to the friction of the disc on the remaining sample surface.

**Alteration of the Discs**
**NC100 Disc**
When cutting the chalk sample, temperature checks (felt by touch) were performed after 5, 15 and 55 min. The disc-sample assembly temperature was cold, cold, and warm, respectively.

Cutting the resin was not a problem. It neither burned nor fouled the disc. The dry cleaning system of the disc allowed relatively good elimination of chalk on the disc despite the strong adhesion of the latter, as shown in the photograph of the disc at the end of the test (Figure 5A).

As previously stated, the test had to be stopped before the sample could be cut completely due to the break in the disc (see Figure 5A). This break is explained by the non-perfect perpendicularity of the disc with respect to the rotation axis. When cutting was resumed after the break, the disc saw had been restarted with the disc in the sample when, in fact, the sample should have been lifted and then placed back onto the rotating blade to take into account this defect of alignment. This lack of perpendicularity also explains the non-homogeneous fouling of the blade visible in Figure 5A. This break is only due the bad alignment of the Pressi P100 disc saw. Normally, these kinds of discs can cut several hundreds of rocks without breaking. Such a failure is not expected with the LithoSpace system and was thus not considered in the following.

**R100-5 Disc**
During dry cutting, both the sample and the disc warmed up. The longer the cutting time, the higher the temperature. In the case of the basalt sample, this resulted in the start of carbonization of the resin as well as of the bristles of the brushes used to remove the dust from the disc (Figure 5B). As these polymeric materials become sticky with heat, the blade cleaning system was less efficient. The disc and the brushes were therefore relatively dirty at the end of cutting, as shown in Figure 5B.

**Surface State**
**Chalk Sample**
Despite the fact that the disc was not perpendicular to the rotation axis, the cut surface of the chalk sample is relatively clean as shown in Figure 6.

In order to study the surface finish, the cutting of the sample was finished using a hacksaw, taking care not to touch the surfaces of the part already cut. A dark halo is observed in the sample (see Figure 6A). This corresponds to the zone of penetration of the resin during induration. The black areas observed are related to burnt polymer from the melting of the bristles of the cleaning system (Figure 6A). In reflected light optical microscopy, the cut streaks are more visible in the indurated zone than in the non-indurated zone (Figures 6B, C). However, AFM analyses show that the average roughness is lower in the indurated zone, 0.1235 µm against 0.302 µm in the non-indurated zone (Figures 6D–G). Due to the technical limitations of the AFM used, it was not possible to perform roughness analyses at a larger scale. These values are therefore largely underestimated. An estimate of the average roughness at the sample scale can be deduced from the
maximum height measured on the AFM images. This gives a roughness of the order of 1.3 µm in the indurated zone and of 2.3 µm in the non-indurated zone (Figures 6F,G).

Chert Samples

Figure 7 shows the surface of the samples after cutting.

The photograph (Figure 7A) shows that the surface finish is particularly homogeneous under the two cutting conditions (1-fast and 2-slow). Very few cutting streaks are observed. In reflected light optical microscopy, the roughness appears to be slightly lower with the slower cutting speed (Figures 7B,C). AFM analyses confirm this difference in roughness, which is 0.156 µm for fast cutting against 0.015 µm for slow cutting (Figures 7D–G). The average roughness at sample scale is estimated to 1.3 µm for fast cutting and 0.95 µm for slow cutting (Figures 7F,G).

Basalt Sample

Figure 8 shows the surface of the samples after cutting.

Cutting streaks are visible in the photograph (Figure 8A). In particular, black areas are observed associated with burnt polymer originating from the bristles of the cleaning system. In optical microscopy, the roughness appears to be low (Figure 8B). AFM analyses show a roughness of 0.094 µm (Figures 8C,D). The average roughness at sample scale is estimated to 1.1 µm (Figure 8D).

Komatiite Sample

Figure 9 shows the surface of the samples after cutting.

The photograph (Figure 9A) shows that the surface finish is relatively homogeneous. Very few cutting streaks are observed. Visually, some areas appear more reflective than others. In reflected light optical microscopy, these two types of surface finish are clearly visible, with reflective areas appearing in light grey (Figure 9C). AFM analyses indicate a significant difference in roughness between the two types of surfaces: 0.206 µm for matt areas against 0.009 µm for shiny areas (Figures 9D–G). The average roughness at sample scale is estimated at 1.1 µm for the matt areas and 0.06 µm for the reflective areas (Figures 9F,G).

Raman Analysis

In order to detect the possible presence of contamination, analyses by Raman spectroscopy were carried out on the various zones studied in Section Surface state (see Figure 10).

Raman analyses of chalk are in agreement with the expected composition, namely calcite with a trace of amorphous silica. Carbonaceous material potentially associated with burnt resin and/or burnt brush bristles is also detected. It is difficult to attribute the unidentified phase with contamination or not. Raman analyses of chert, basalt and komatiite are in agreement with the expected compositions. No contamination was detected. For the komatiite sample, the difference in surface finish between the matt and the reflective areas is not associated with difference in composition.

DISCUSSION

Conclusions on Cutting Tests

Table 2 summarizes the various parameters and results associated with each cut. We define in particular:

1) The basic consumption, which is the consumption of the system powered on, all engines off. This consumption is linked to the design of the instrument (electronics, indicator lights, etc.). With a view to develop a space instrument, this can be greatly reduced.

2) The power without sample, which corresponds to the consumption of the system switched on before cutting the sample. This consumption is linked to the speed of the engines and to their design (quality of bearings, friction, loss by Joule heating, etc.). This consumption can therefore be greatly reduced too.

3) The maximum power, which corresponds to the maximum consumption of the system reached during cutting.

4) The useful power without sample, which is the consumption only attributable to the engines when they are running but
without cutting. It corresponds to the power without sample minus the basic consumption.

5) The maximum useful power, which is the maximum consumption attributable to the engines during cutting. It corresponds to the maximum power reached minus the basic consumption.

6) The minimum power, which is the minimum power required to cut the sample. It corresponds to the maximum useful power minus the useful power without sample. This power corresponds to the minimum power required to cut the sample for given $v_d$ and $v_s$ speeds.

The parameter that most influences the power required to cut a rock is the load, represented here by $v_s$. The greater the sample force on the disc, the more the system consumes power, as clearly shown by the two cuts made in the chert sample. It is thus preferable to cut with a constant load, as for the Pressi P100 saw, rather than with a constant sample displacement speed, as with the Struers Secotom-100 saw. Nevertheless, the load must be high enough to cut the rock in a reasonable time. A compromise must therefore be found between cutting time and load.

The absence of water has several consequences. First, the disc and sample could not cool down and the temperature increased. The greater the load, the greater the heating. Secondly, dust is not efficiently removed from the cut line and fouls the saw, which becomes less sharp. This increases the friction between the disc and the sample resulting in the increase of the temperature and of the load when working at constant sample displacement speed.
Thus, despite identical cutting parameters, the power consumption is much greater during dry cutting of the komatiite sample than during the second cutting of the chert sample. Consequently, it is important to note that, in the absence of water, the hardness is not the relevant parameter to consider to evaluate the capacity of a system to cut a rock but rather its propensity to stick to the saw when cut. It would thus be potentially easier to cut a chert than a mudstone, for example.

The surface finish of the samples after cutting is related to roughness and contamination. Roughness depends on several factors. The nature of the sample plays an important role as evidenced by cutting tests performed on chalk and komatiite. Cutting tests carried out on chert show that a high load tends to increase the surface roughness. However, for all the tests, the “large” surface roughness remains very limited (less than 2 µm), meaning that the rock can be glued onto the glass slide directly after cutting as envisioned in the proposed protocol (cf. Figure 2), i.e., no lapping is required.

Contamination of the sample is related to the absence of water. The disc scrubbing system used did not efficiently remove cut-off residues, which remain attached to the brushes and induce contamination from one sample to another. The polymer bristles melted and then burned, partially contaminating the samples and the disc. This can be strongly improved by using, for example, a pumice jaw system that would remove dust from the blade during cutting. Nevertheless, cutting and grinding

![Figure 7](https://example.com/figure7.png)

**FIGURE 7** Chert samples after cutting with the Struers Secotom-10 disc saw. (A) Photograph of the three pieces of sample. (B,C) Optical microscopy images in reflected light of the areas indicated in (A). (D,E) AFM images of the areas indicated in (B,C) respectively and (F,G) associated roughness measurement.
activities generate a lot of dust and it would be necessary to find a way to clean the tools between each use, as well as the thin sections before observation.

Finally, this study shows that it is possible to cut samples, including very hard rock, such as cherts, with a system whose power is less than 150 W. Moreover, it is important to note that the systems used for the tests are relatively large and are not as optimized as a space system would be.

Towards a Space System
The cutting tests demonstrated the feasibility of cutting a rock sample without water and with a relatively limited power. Most of the difficulties encountered can be circumvented by controlling the load applied to the sample and the temperature and by adding an efficient disc and sample cleaning system. We thus focussed the further investigations on the automation of the protocol described in section Envisioned protocol (see Figure 2). As displayed in Figure 11, we propose a system composed of three superimposed discs which can rotate independently from each other. The upper disc contains the glass slide distribution system and holder. The middle disc 2 has a notch to hold the induration tank and a brush to remove dust from the sample surface. Finally, the lower disc is composed of an empty section and 3 sections of various thicknesses permitting vertical displacement of the tank. Above these three discs are the sample arrival chute from which the drill cores arrive, the induration tank dispenser, the resin dispenser and the sawing area with a retractable disc saw located vertically between the discs 3 and 2. The bottom part of the system is composed of the microscope objective (or any other instrumental probe), the polishing disc, the grinding disc and the bin to store the cutting residues. By rotating the discs, it is possible to make and observe a thin section according to the different steps described in Figure 11. All along the preparation the orientation of the sample is known based on the images made outside the rover.

System Improvement
In the absence of time constraints—the device is not yet designed for a specific mission—the opportunity was taken to use this project as a support for teaching. Thus, students in fifth year at the engineering school Polytech', University of Orleans, and students in BTS (2-year technical degree) “Industrialization of Mechanical Products” and in
professional license of “Technical Coordinator of Industrialization Methods” from the Benjamin Franklin high school of Orléans, worked on the optimisation of the system and on the development of a demonstration model. Different optimisations proposed are displayed in Figure 12.

Tank Distribution and Maintaining System
The tanks are used to indurate the drill cores. One tank is required per sample. In the proposed system (Figure 12A) the tanks are stored vertically and a cylinder is used to insert one of them into disc 2. The tank is maintained in the disc using springs and valves. This solution offers the advantage of using only a single actuator.

Resin Distribution System
Consideration was given to a system allowing the mixing of a standard polyepoxy resin (Araldite 2020). This resin is compatible with vacuum and may harden at relatively low temperature (until 10°C), thus requiring low heating. UV hardening resins were not considered because they are not compatible with opaque rocks. Cyanoacrylate glues were not considered because their hardening requires liquid water (humidity). The system proposed in Figure 12B is composed of two compartments, one containing the epoxy resin and the other the hardener. Valves allow the application of the correct amount of resin and hardener in a chamber with a mixing rod. Cylinders allowing the application of the products from the side.
FIGURE 10 | Raman analyses of the samples after cutting. For each sample, the analysed area is denoted by a small white square in the reflected light micrograph on the left. (C) Raman spectroscopy compositional map with calcite in pink, amorphous silica in yellow, carbonaceous material in green and an unidentified phase in red. (D,E) reflected light optical microscopy images of the non-indurated area of the chalk sample. (F) Raman spectroscopy compositional map showing only calcite in pink. (G,H) reflected light optical microscopy images of the chert sample (slow cut). (I) Raman spectroscopy compositional map with muscovite in fuchsia, anatase in dark blue, carbonaceous material in green, and quartz in orange. (J,K) reflected light optical microscopy images of the basalt sample. (L) Raman spectroscopy compositional map with augite in fuchsia, labradorite in light blue, hematite in red, and apatite in yellow. (M,N) reflected light optical microscopy images of a matt part of the komatiite sample. (O) Raman spectroscopy compositional map with talc in pink, antigorite (serpentine) in fuchsia, and carbonaceous material in green. (P,Q) reflected light optical microscopy images of a bright part of the komatiite sample. (R) Raman spectroscopy compositional map with talc in pink, antigorite (serpentine) in fuchsia, and carbonaceous material in green.
chambers are also present if the low gravity of the explored extraterrestrial body is not enough to permit a natural flow of the liquids. Finally, the central chamber consists of a cylinder for the application of the product. An engine rotates a mixing rod while at the same time pushing down the mixture onto the sample. This nice solution is however relatively complex to implement and it is probable that single-dose syringes would be preferred in the final version of the system.

Cutting System
There are two possibilities for the cutting phases: either they are carried out at constant sample displacement speed, or they are carried out at constant load. Nevertheless, previous experience has demonstrated that it better to work at a constant load in order to limit heating and also because of potential sample inhomogeneity. The chosen solution presented in Figure 12C consists of an engine rotating the disc saw and a cylinder pushing the disc saw onto the sample to be cut at a constant load.

Glass Slide Distribution System
The technical solution displayed in Figure 12D is very close to the tank distribution system described in Section Tank distribution and maintaining system. A cylinder is used to push the glass slide into the disc 3. The shape of the slides is designed in order to be slid into the thickness of the disc. Once a thin section has been analysed, it is pushed by the next one and falls into the bin or into a storage system.

Evacuation System
After the second cut (step 8), in order to obtain a 100 µm thick section, it is necessary to evacuate the bottom of the tank; however, this part of the sample is held in the cavity due to the springs present in the disc 2 (see Figure 12A). In order to facilitate its evacuation, a cone mounted onto a spring is added in the disc 3 as illustrated in Figure 12E. It permits pushing down of the bottom part for the tank into the bin as it passes underneath. An identical system is also in the disk 3 to evacuate the top part of the sample in step 5.

Grinding and Polishing System
In order to avoid creating scratches, grinding and polishing systems generally use a combination of at least two rotation motions (e.g., by rotating both the disc and the sample). In order to reproduce this double movement, the double axis rotation system shown in Figure 12F has been proposed. It can also be envisioned to use a disc having an outer abrasive area for grading and an inner abrasive area for polishing as proposed by Dreyer et al., 2013 and Paulsen et al., 2013.

Disc Rotation System
The solution displayed in Figure 12G consists in notching the discs on their outer periphery. The discs are in contact with notched discs that can be connected to a rotating drive shaft using solenoid valves. When a solenoid valve is in the top position, a bevel gear comes into contact and transmits the motor torque to the notched disc which in turn drives the corresponding disc. This solution allows easy synchronization for steps requiring the rotation of several plates at the same time while allowing independent rotations with a single motor, in both directions of rotation. It therefore represents a saving in terms of weight and size compared to a solution requiring 3 separate engines.

Demonstration Model
As noted above, the project is still in progress and we are far from the development of a working system. Nevertheless,
FIGURE 11 | LithoSpace system. (A) The system is composed of three superimposed discs which can rotate independently of each other. The upper part of the system is composed of the sample arrival chute, from which the drill cores arrive, the induration tank dispenser, the resin dispenser, and the sawing area with a retractable disc saw. The upper disc (disc 3) is only 2/3 full. It contains the glass slide dispenser and holder. There is an empty mould on its underside to maintain the tank holder during sawing. Disc 2 is also 2/3 full. It has a notch to hold the induration tank and a brush to remove dust from the sample surface. The lower disc (disc 1) is composed of an empty section and 3 sections of various thicknesses permitting vertical displacement of the tank: $e$ typically $e = 1$ cm, $e + h/2$ with $h$ the induration tank thickness (typically $h = 1.5$ cm), and $e + h/2 + 100$ µm. Finally, the bottom part of the system is composed of the microscope objective (or any other instrumental probe), the polishing disc, the grinding disc and the bin to store the cutting residues. (B) By moving the discs it is possible to make and observe a thin section in 12 steps as described in (C). 1- An induration tank is inserted from the tank distribution system in the dedicated hole in disc 2, onto the part of thickness $e$ of disc 1. 2- The three discs rotate to place the tank below the arrival chute from which the drill cores fall. The tanks have a triangular profile in such a way that the cores necessarily fall in a centred position. 3- The three discs rotate to place the sample below the resin dispenser and the core is covered with resin and indurated. 4- Disc 3 is positioned so that the hollow on its lower part is aligned with the tank then disc 1 is positioned on the part of thickness $e + h/2$ so as to bring up the tank which then becomes wedged in disc 3. Finally, the tank plus the drill core assembly is cut through its middle. 5- The three discs rotate to place the sample below the resin dispenser where resin is deposited onto the cut surface of the sample. 7- A glass slide is slid into the slide holder. Disc 1 then raises the sample half the thickness of the tank plus 100 µm so that it is glued onto the glass slide (part of the disc of thickness $e + h/2 + 100$ µm). 8- The sample is cut again to a thickness of 100 µm relative to the surface of the glass slide. 9- The three discs rotate to the “bin” position and disc 3 is rotated on its empty part to evacuate the bottom part of the sample. 10- The section is ground in order to correct the parallelism of the faces and to reduce its thickness to ~32 µm. The grinding stop is controlled by a circuit breaker. 11- The thin section is polished in order to decrease the roughness and to reach the final thickness of 30 µm. 12- The polished thin section is presented to the observation/analytical system(s). The position of the discs during the different steps are detailed in (C). The stars indicate the position of the sample.
much progress has been made. In order to promote the project, it was thus decided to develop a demonstration model serving as a "proof-of-concept." Thus, still in collaboration with the students from the Benjamin Franklin high school, a physical model in polycarbonate was made to be presented to the public as displayed in Figure 13. Samples, as they would be at the different steps, have also been prepared (see Figure 13C).
planned to motorize this model in order to make it “functional” in the near future.

**CONCLUSION**

The possibility to analyse petrographic thin sections *in situ* on extraterrestrial bodies would constitute an important advance in space exploration. In particular, it will permit structural and textural study of a rock, fine scale mineralogical analysis, and, with respect to Mars, detection of putative traces of fossilised microbial life. It would also open up the possibility of multiple techniques, from optical microscopy to micro-Raman and micro-LIBS imaging. With these advantages in mind, we proposed development of an automated thin sections maker for *in situ* space exploration in the framework of the LithoSpace project.

Among the difficulties considered were the absence of liquid water, the power consumption and the automation of the standard protocol. Using a series of tests, we demonstrated the feasibility of cutting rocks of various hardness and competency without water, and using power consumption compatible with space probe. We then proposed a system to carry out the automated protocol in a limited volume using three superimposed discs rotating independently to each other. Technical solutions were then proposed for the different steps by students from the Polytech’ engineering school and from the Benjamin Franklin high school. Finally, a demonstration model serving as a “proof-of-concept” to be presented during congresses has been made and was already shown at the 42nd COSPAR meeting in 2018 in Pasadena, United States, and during the European Planetary Science Congress 2018 in Berlin, Germany. The project was very well received by the scientific community, which was particularly enthusiastic about the possibility to analyse thin sections *in situ*.

Finally, even if the system has been initially though for automated space missions, it could be particularity useful for future human exploration. Indeed, its small bulk facilitates its incorporation within future extraterrestrial habitats. Similarly, the system could be relevant for the preparation of thin sections from the samples bring back to Earth during sample return missions by facilitating the preparation in sterile conditions. More broadly, a compact all-in-one thin section preparation system would be of interest for scientific field exploration on Earth, as demonstrated by the portable thin section preparation laboratory (non-automated) proposed before by Goren (2014).

**DATA AVAILABILITY STATEMENT**

The authors confirm that the data supporting the findings of this study are available within the article. The raw data are available on request from the corresponding author, FF.

**AUTHOR CONTRIBUTIONS**

FF supervised the project, conceptualized the protocol and the system, make the experiments and wrote the original draft. NB supervised the project, conceptualized the protocol and the system, make the experiments and review the original draft. SJ conceptualized the protocol and the system, make the experiments and review the original draft. AF supervised the students from Polytech’ engineering school, conceptualized the protocol and the system and review the original draft. NL review the original draft. PP, MB and FL supervised the students from the Benjamin Franklin high school, conceptualized the system.
and review the original draft. MV, PC, FC, and MV conceptualized the protocol and the system and review the original draft. FW supervised the project and reviewed and corrected the original draft.

**ACKNOWLEDGMENTS**

We thank the CNES for funding. We thank the CEMHTI laboratory for the use of the Presi P100 and Struers Secotom-10 systems. We thank the students for their contribution: Jianyu Li and Thomas Platel from Polytech’ Orléans, France, and Charles Fidanza, Laël Ibala, Clémence Navereau, Stanislas De Olivera, Nicolas Pricott, Romain Segret, Baptiste Smeets, Ulysse Tastet, Adrien Tessier-Neiel, Quentin Truchot, and Vincent Vaidie from the Benjamin Franklin high school, Orléans, France.
