ABSTRACT
Humans have paid a lot of attention to environmental geological challenges in recent years. Landslides, being one of the most prevalent geological disasters, are characterized by their suddenness and destructiveness. Southwest China is prone to landslides and debris flows due to its unique geological structure. This paper uses landslides in southwest China as an example, focusing on research on landslide initiation mechanisms and outlining modern landslide monitoring devices and prediction models. Landslides are caused by external variables such as persistent precipitation, groundwater movement, and significant seismic activity, as well as interior reasons such as fine particle rearrangement and the action of positive pore water. The reduction of the friction coefficient of the shear surface, which is induced by the increase of the shear rate, the supercritical carbon dioxide and superheated steam impact on reducing the friction coefficient of the shear surface, is a key factor in the occurrence of high-speed remote landslides. Real-time landslide monitoring using space-air-ground and acoustic emission technology, as well as the creation of machine learning-based forecast models, have aided in the research of landslide development and early warning.

INTRODUCTION
Southwest China is located on the east side of the Qinghai-Tibet Plateau. Various geological factors have influenced the formation of a complex geological environment and valley dynamic conditions over time, including high ground stress, strong fault structure-activity, frequent strong earthquakes, the dynamic characteristics of a strong river in a deep-cut canyon, the complex rock-soil environment, and hydrogeological conditions, and the deep overburden of the river bed, among others. After the Wenchuan earthquake in 2008, the frequency of these geological disasters has increased significantly, which provided a lot of data for the study of debris flow (Li et al. 2021a, 2021b, 2021c, Peng et al. 2021, Hu et al. 2014, 2016, 2018a, 2018b, 2018c, 2018d, Liao et al. 2020, 2021, Liu et al. 2020, 2021, Chang et al. 2021).

The international definition of a landslide isn’t agreed upon. Simply put, a landslide is a natural geological phenomenon in which the rock and soil mass on a slope slide downward along a weak surface or zone under the action of gravity (Nemok et al. 1972, Varnes 1978), and its action process is one of the manifestations of the geomorphology evolution process (Glade & Crozier 2005, Irasema 2002).

The landslide’s massive volume is usually large, which is owing not only to the rock and soil being transported by themselves but also to the entrainment effect of the landslide movement process, which causes the ultimate landslide body volume to be much larger than the initial volume (Gao et al. 2020). Because the dangers of landslides are self-evident, an in-depth study of existing landslides can guide future landslide prevention and management, and it is also a manifestation of humans learning from and modifying nature. Shao et al. (2020) studied the identification, classification, and characteristics of landslides in Baoshan City, Yunnan Province, China, and established a detailed landslide list, which provided the necessary basis for further study of landslide development and spatial distribution, landslide prediction, and geological disaster evaluation in Southwest China. According to satellite images, there was an ancient landslide in this area before 2008. Wasowski et al. (2021) studied the Yangjiagou landslide formed after Wenchuan Earthquake and combined it with the existing landslide research. Finally, the seismic activity pattern in the surrounding area of the Longmenshan fault was inferred, and other works of literature also reported it (Ouimet 2010; Tang et al. 2011, 2012; Fan et al. 2018, 2020). Wang et al. (2021a, 2021b)
conducted a field investigation and experimental research on
the occurrence mechanism of the Donghekou landslide, and
the results obtained were used to guide landslide research
in Japan. iRALL also organized a thematic meeting on the
issue of landslides after the 2008 Wenchuan earthquake
(Huang et al. 2018).

In this paper, the current developments in the study of
landslide occurrence mechanisms are strongly introduced,
and finally, numerous approaches and models for landslide
monitoring and prediction are summarized, with a focus on
typical landslides in Southwest China. We know the land-
slide-prone locations, the landslide occurrence mechanism,
expand the depth and breadth of the study mechanism and
compare the accuracy of monitoring means and forecasting
models from a macro perspective. It helps us to have an
overall understanding of the existing prevention and control
methods, to guide the prevention and control of landslide
disasters.

**Landslide Mechanisms**

**Influencing factor:** The occurrence of landslide needs to
meet specific mechanical conditions, that is, when the sliding
resistance of the weak surface of landslide is less than the
sliding force, a certain volume of rock and soil will move
along the sliding surface. The mechanism of landslides is
closely related to the inducing factors. Table 1 depicts the
conditions that may cause a landslide from four perspectives.

**Mechanisms of the Soil landslides:** When the landslide
material is made up of a loose accumulation of dirt, it
would start up and move like water under the impact of an
earthquake or a high-intensity continuous rain. To study its
mechanism, Hu et al. (2017a, 2017b, 2018a, 2018b, 2019)
experimented with artificial imitation particle slope in the
laboratory and revealed the instability and failure mechanism
of this system. Hu et al. (2016, 2019, 2020) also believed
that under gravity, a precise combination of normal stress and
shear strain rate would cause dry particle flow to move, and
that particle breaking would considerably lower following
shear resistance due to particle thixotropy.

In addition to the influence of soil particle size, the
excessive positive pore water pressure in a landslide is also
considered as one of the important factors triggering landslide
(Wang et al. 2020), so the monitoring of on-site pore water
pressure can be used as a reliable indicator for landslide
early warning (Hu et al. 2017a). Hu et al. (2017b) studied
the influence of particle size and pore water on the start of
landslides. As mentioned earlier, precipitation often plays a
key role in the occurrence of landslides, and its time evolution
has a positive correlation with the landslide process (Wang
et al. 2019, Yang et al. 2019, Gao et al. 2020, Li et al. 2020).
Besides precipitation, terrain factors also have a significate
influence on the occurrence of landslides (Fan et al. 2020).
For reservoir landslide, Wang et al. (2021a, 2021b) and Li
et al. (2021a, 2021b, 2021c) have reached similar conclu-
sions, namely, the dominant failure mechanism of landslide
changes with the change of reservoir water level and slope
saturation. The periodic fluctuation of reservoir water level,
according to Liao et al. (2021), has a significant impact on
the mechanical characteristics of the sliding zone in the
water-fluctuating zone, and the area of the water-fluctuating
zone regulates landslide stability. Xia et al. (2021) introduced
a two-dimensional Discontinuous Deformation Analysis

| Geological factor                      | Geomorphological factors       | Natural factors         | Human factors          |
|---------------------------------------|---------------------------------|-------------------------|------------------------|
| soft rock-soil                        | Structure or volcanic uplift    | Rainstorm               | Excavation of slope and slope foot |
| weathered rock                        | Ice cover spring back           | Quick snowmelt          | Loading weight on slope or slope top |
| shear band cutting rock mass          | River erosion slope toe or its side edge | continuous rainfall | reservoir construction |
| Rock mass with developed joint fissures | Wind erosion slope toe         | Flood or tidal impact   | disafforestation       |
| Reverse discontinuity surface ( fault, unconformity surface, fracture, etc. ) | Ice erosion slope toe          | Earthquake              | irrigation             |
| Significant difference in permeability of rock-soil | Underground erosion (dissolution and sub-erosion) | volcanic eruption | Mining, quarrying      |
| Significant difference in the strength of rock-soil | Vegetation destruction | melting ice             | artificial vibration   |
|                                      | Slope or slope top stacking interaction | Freezing and dissolved conduit leakage | shrinkage and swelling |

Table 1: The factors affecting the occurrence of landslides (Cruden & Varnes 1996).
Mechanisms of the rock landslides: Rock landslides are also common in the Sichuan Basin and the Three Gorges area of China. The typical feature of this kind of landslides is the alternating layers of mudstone and sandstone in a bedrock-control cataclastic slope. Hu et al. (2019, 2014, 2016) studied the starting mechanism of the Daguangbao landslide formed after the Wenchuan earthquake, it was found that the high temperature of 800°C was generated during the sliding process of the basement, which made dolomite thermally decompose to form lime (CaO) and magnesia (MgO) (Fig. 1), and some minerals in the shear zone were heated to form a dynamic recrystallization layer about 0.1 mm thick (Fig. 2).

In addition, hot supercritical carbon dioxide and superheated steam with a pressure of > 10MPa could produce high pore-fluid pressure, and the dynamic recrystallization of minerals and supercritical gas together constituted the drag reduction mechanism of landslide movement, which was consistent with Habib (1975) and Goguel (1978). As a result, quick long-run-out landslides are easy to form. Hu & McSaveney (2018) and Hu et al. (2018b) then conducted extensive investigations into two rock failures in Jiweishan and came to the same result. This is because as soil saturation and shear rate increase, the residual friction coefficient of the soil decreases significantly, and the critical stress triggering large displacement is related to the residual shear strength related to soil rate (Hu et al. 2018a, Scaringi et al. 2018), while another paper (Xu et al. 2021) shows that under the action of larger normal stress (> 100kPa), the soil in the slip zone is more likely to fail than the soil-bedrock interlayer.

Landslide Monitoring and Prediction

Landslide activity can be observed in all weathers using monitoring equipment based on the integration of space, air, and ground. Landslide prediction models have been swiftly constructed using a combination of statistics and computer science, and their accuracy and scope of application have been greatly upgraded and enlarged, as described in this study.

Monitoring technology: Interferometry Synthetic Aperture Radar (InSAR) is a real-time landslide monitoring system that has been successfully utilized for landslide monitoring in Southwest China (Zhang et al. 2021, Woods et al. 2021). Hu et al. (2018a) discovered a creep-like link between acoustic emission technology and density and cumulated acoustic energy of slope material by capturing and analyzing the high-frequency atomic spectrum generated by particle rearrangement in landslides. The literature also mentions sonic emission technology as an early warning approach for landslide monitoring (Xiaoyan et al. 2020). The dam height of the dammed lake generated by the second landslide is larger when more than two landslides occur in the same location on both bank slopes of the river, but its stability is lower (Liao et al. 2020). As a result, it is vital to estimate the landslide risk in the area, predict the likely dammed lake shape, and execute control measures ahead of time to minimize damage. As demonstrated in Tables 2, 3, and 4, it separates the monitoring technical principles, benefits, and drawbacks of space-air-ground monitoring.

![Fig. 1: Electronic image of sliding surface and internal structure in cataclastic dolomite near the sliding surface of Daguangbao landslide. a. Two sets of micro-scratches, vertical scratches indicate the direction of landslide movement; another group of scratches may be the direction of past tectonic movement. b. and c. The remains of formerly decomposed dolomite grains (now reconstituted) (Hu et al. 2019).](image-url)
Prediction models: It is far from sufficient to rely exclusively on monitoring technology to avoid and control landslides. Because precipitation has such a large impact on the commencement of a landslide, some researchers (Yang et al. 2019, Yu et al. 2020) suggested a precipitation threshold prediction model and verified its validity with existing data, resulting in an excellent prediction result. Liu & Wang (2021) simulated the whole process of a landslide caused by rainfall, which provided a new perspective for the quantitative risk assessment (QRA) study of landslide-induced landslides. In recent years, machine learning has played an increasingly important role in fuzzy reasoning and data statistics. For instance, the neural network model (Abbaszadeh et al. 2020, Liu et al. 2021), neuro-fuzzy reasoning, and ant colony algorithm (Razavi-Termeh et al. 2021) have great advantages in evaluating landslide susceptibility. Zhou et al. (2018) combined the support vector machine (SVM) and artificial neural network (ANN) with multivariate statistical model logistic regression (LR) to propose the landslide susceptibility modeling (LSM). Goetz et al. (2015) and Chen et al. (2018) respectively selected six and four landslide sensitivity evaluation models based on machine learning. Sun et al.

Table 2: Monitoring methods on space.

| Monitoring methods                  | Principle                                                                 | Advantages                      | Disadvantages                                                                                   |
|------------------------------------|--------------------------------------------------------------------------|---------------------------------|-------------------------------------------------------------------------------------------------|
| Global Navigation Satellite System, GNSS | The position of the monitoring point is acquired by satellite in real-time | 24h-monitoring; all-weather     | The number of monitoring stations is limited and the data processing process is complex          |
| Interferometry Synthetic aperture radar, InSAR | The image of the landslide is obtained by SAR satellite, and then the three-dimensional terrain information of the landslide is obtained by processing the photo | 24h-monitoring; all-weather; high precision | It is difficult to select monitoring points, which is affected by spatial loss correlation and atmospheric delay |
| Unmanned Aerial Vehicle, UAV       | The UAV is equipped with a camera, flies along the design route and takes pictures, and then obtains a three-dimensional slope model through the image data processing | High precision, automation, intelligence, not affected by clouds | It cannot be monitored all-weather due to the weather                                              |

Fig. 2: Electronic images of internal structures at different depths under the sliding surface in cataclastic dolomite of Daguangbao Mountain. a. Dolomite fragments under the sliding surface. b. and c. Skeletal remains of extensively decomposed dolomite. d. Partially decomposed dolomite fragments covered with tiny spheres (nano-sphere) typical of thermal decarbonization of dolomite to lime (CaO) and magnesia (MgO) (but now carbonated in the nine years’ exposure) (Hu et al. 2019).
(2021) established two optimized landslide susceptibility mapping models (LSM): logistic regression (LR) and random forest (RF) based on Bayesian algorithm hyper parameter optimization. In terms of landslide distance prediction, Zhou et al. (2020) proposed an optimized neural network model whose advantages are significantly greater than the multiple regression model. Li et al. (2021a, 2021b) used PFC software to predict the runout behavior of landslides and provided a new method for landslide hazard risk assessment.

CONCLUSION

In this paper, the present situation of landslide research in Southwest China is summarized, with emphasis on the landslide starting mechanism, and a brief overview of landslide monitoring technology and prediction model.

1. There are many factors contributing to the initiation of landslide, among which precipitation and earthquake are two major inducing factors. For soil landslide, precipitation leading to seepage in the landslide and fine particles recombined by water migration induces deformation of landslides to a certain extent. On the one hand, the stability of a landslide could be broken by an earthquake. On the other hand, the positive pore water pressure in a landslide may rise due to vibration, which will also trigger a landslide. Rock landslide has the characteristics of fast speed, long-distance, and large volume because high temperatures are generated in the shear zone of a landslide during movement, the minerals at a certain thickness of interface dynamically recrystallize, and high temperatures also produce supercritical carbon dioxide and superheated steam, lowering friction coefficient and friction resistance. The friction coefficient of the shear surface will also decrease with the increase of normal stress and shear rate during the movement of soil landslide.

2. It’s a quick rundown of landslide monitoring and forecasting technology. Landslide monitoring technology evolves in tandem with scientific and technological advancements. Real-time landslide monitoring and accurate forecasting will advance to a new level if the integrated monitoring technology in the space-air-ground can be fully employed. The landslide prediction model is mainly based on statistical analysis and machine learning to make a landslide susceptibility model (LSM), combine the model with existing landslide data, and constantly adjust parameters to achieve

| Monitoring methods | Principle | Advantages | Disadvantages |
|--------------------|-----------|------------|---------------|
| Robot monitoring   | The total station automatically monitors the prism on the landslide in 24 hours | Automation, 24-hour monitoring, high precision | The monitoring range of a single robot is small, but the cost of arranging multiple robots is high |
| 3-D laser scanning | By measuring the time difference between transmitting and receiving laser and the horizontal angle and zenith distance of each pulse laser, the three-dimensional coordinates of the measured object are obtained | 24-hour dynamic monitoring; high precision | The data processing is complex and the measurement accuracy is affected by surface objects |
| GB-InSAR          | The LIDAR sensor emits and receives microwave signals, and the image is synthesized by SAR technology. | High precision; 24 h monitoring; all-weather; not affected by the weather | Lack of data processing; monitoring environment has an impact on the results |

Table 3: Monitoring methods on air.

| Monitoring methods | Principle                                                                 | Advantages                              | Disadvantages                                      |
|--------------------|---------------------------------------------------------------------------|-----------------------------------------|----------------------------------------------------|
| Time Domain Radiation, TDA | The deformation position and displacement can be determined by processing the echo signal. | Short monitoring time, low cost, and accurate positioning of sliding surface | Unable to determine the position of the sliding surface, low sensitivity to uniform deformation, point style monitoring |
| Borehole inclinometer | There is a certain angle between the inclinometer probe and the deformation of rock and soil, and the horizontal displacement of the inclinometer probe can be calculated by using the angle. | Accurately monitor the direction of sliding surface | Point monitoring, orientation is susceptible to interference |
| Distributed fiber optic sensing | Through the reception and analysis of scattered light, the changes of strain and temperature in optical fiber are obtained | High precision, distributed monitoring, high survival rate, anti-corrosion and anti-interference | Unable to determine the direction of sliding surface |
the expected accuracy. However, due to the limitations of the existing technology, no model can accurately predict all types of landslide characteristics.
