Learning Dense Rewards for Contact-Rich Manipulation Tasks

Zheng Wu¹,², Wenzhao Lian¹, Vaibhav Unhelkar³, Masayoshi Tomizuka² and Stefan Schaal¹

Abstract—Rewards play a crucial role in reinforcement learning. To arrive at the desired policy, the design of a suitable reward function often requires significant domain expertise as well as trial-and-error. Here, we aim to minimize the effort involved in designing reward functions for contact-rich manipulation tasks. In particular, we provide an approach capable of extracting dense reward functions algorithmically from robots’ high-dimensional observations, such as images and tactile feedback. In contrast to state-of-the-art high-dimensional reward learning methodologies, our approach does not leverage adversarial training, and is thus less prone to the associated training instabilities. Instead, our approach learns rewards by estimating task progress in a self-supervised manner. We demonstrate the effectiveness and efficiency of our approach on two contact-rich manipulation tasks, namely, peg-in-hole and USB insertion. The experimental results indicate that the policies trained with the learned reward function achieves better performance and faster convergence compared to the baselines.

I. INTRODUCTION

Reinforcement learning (RL) has shown promising performance on a variety of complex tasks, ranging from playing video games to vision-based robotic control [1], [2], [3]. However, the success of RL techniques relies heavily on the availability of high-quality, dense reward signals. Learning policies on tasks with sparse rewards, such as Montezuma’s revenge [2], remains notoriously challenging. In robotics, these dense rewards often need to be hand-crafted by a human. This reward engineering typically requires significant domain expertise as well as trial-and-error. In contact-rich manipulation tasks, due to the discontinuous dynamics and high-dimensional observation spaces, the challenge of reward specification is further amplified; thus, making the adoption of RL methods for robotic manipulation difficult in practice.

The goal of our work is to reduce the effort involved in reward specification for contact-rich manipulation tasks, such as peg-in-hole and connector insertion [4]. Inverse reinforcement learning (IRL) techniques, which learn reward functions from expert demonstrations, offer one such alternative to circumvent the challenge of reward engineering [5]. However, classical IRL techniques require hand-engineered states or features, making their application to tasks with high-dimensional and continuous observation spaces (such as camera images and tactile feedback) challenging [5], [6], [7].

More recently, by leveraging generative adversarial learning [8], IRL techniques have been developed to address continuous [9], [10], high-dimensional observation spaces [11], [12], and successfully demonstrated on robotic manipulation tasks. However, despite their encouraging performance, this class of methods inevitable inherits the instabilities associated with adversarial training [13] and fail to utilize multi-modal observations.

To learn reward functions for contact-rich manipulation tasks while avoiding the challenges of generative adversarial learning, we propose a novel approach **Dense Rewards for Multimodal Observations (DREM)**. Several contact-rich manipulations tasks can be specified through sparse reward signals, such as a goal state or a Boolean measure of task success (e.g., a peg being inside a hole, electricity passing through a connector and socket pair). While these readily available sparse reward signals are often insufficient for sample efficient high-dimensional RL, they can help design dense reward signals when coupled with expert demonstrations or, even, self-supervision. Our approach, thus, combines a sparse reward signal, self-supervision, and (optionally) observation-only expert demonstrations to extract a dense reward function. This dense reward can then be used with any appropriate RL technique to arrive at the robot policy.

Given the sparse measure of task success and optional expert demonstrations, DREM learns a mapping from the high-dimensional observation space to a latent measure of
task progress. For an arbitrary robot observation, this latent measure aims to provide its task-specific distance to the goal state, thereby serving as a proxy for the dense reward signal. Intuitively, our approach builds on the insight that a state that is closer to the task goal (in a task-specific metric) should be assigned a higher reward than one that is farther, as shown in Fig. I. Our core contribution is to realize this insight computationally for high-dimensional, multimodal, and continuous observation spaces. DREM achieves this by first creating a dataset of observations and their corresponding task progress (latent space labels) through an efficient, self-supervised sampling process. This dataset is then used to train an encoder-decoder network, attain a latent space, and obtain the dense reward function.

We evaluate the proposed approach to reward learning on two representative contact-rich manipulation tasks: peg-in-hole and USB insertion. In these evaluations, DREM learns the reward using only one expert demonstration. The learned reward function is then used to generate robot policies using Soft Actor-Critic, a model-free RL algorithm [14]. Experimental results show that the policies trained with our learned reward achieve better performance and faster convergence compared to baseline reward functions, including those obtained by recent reward learning approaches.

II. PROBLEM STATEMENT

A. Tasks of Interest

Motivated by near-term applications in assembly, we focus on contact-rich robotic manipulation tasks. In particular, we consider tasks that can be suitably modeled as discrete-time Markov decision processes (MDPs) [15]. Briefly, MDPs describe sequential decision-making problems and are parameterized via the tuple $\mathcal{M} = (\mathcal{S}, \mathcal{A}, \mathcal{T}, R)$, where $\mathcal{S}$ corresponds to the state space, $\mathcal{A}$ corresponds to the action space, $\mathcal{T}$ denotes the transition model, and $R(s) \rightarrow \mathbb{R}$ represents the real-valued reward of state $s$.

In contact-rich manipulation tasks, the state space is composed of high-dimensional, continuous observations available from robot sensors. The robot observation is typically multimodal, e.g., visual (through cameras), tactile (through force-torque sensors), and proprioceptive (through measurements of joint angles and velocities). The action space models the actuation capability of the robot. Prior works have explored a variety of action spaces across the joint space, the operational space, and their combinations [16]. Our problem is agnostic to the specification of the action space. In our analysis, without loss of generality, we model actions as the end-effector twist (linear and angular velocity) of the robot.

The transition model represents the physics of the environment. Due to the task being contact-rich, the model is highly non-linear, potentially discontinuous, and difficult to specify analytically. This motivates the need for model-free RL techniques. The objective of an agent solving the MDP is to arrive at a policy $\pi(s) \rightarrow a$ that maximizes its expected cumulative reward. Several contact-rich manipulation tasks encountered in the manufacturing domain can be suitably described by the above MDPs, such as peg-in-hole, connector insertion, and gear assembly [4].

B. Inputs and Outputs

Assembly tasks are typically categorized by their repeatability and presence of a goal state $s_G$, which can be used to arrive at a sparse reward (i.e., a positive value at $s_G$ and zero otherwise). We denote this sparse goal reward as $R_G$. However, as motivated in Section I, this sparse signal is often inadequate for learning the policy for high-dimensional continuous MDPs, requiring prohibitive amounts of exploration. Instead, to achieve sample efficiency, RL techniques require a richer reward signal that can guide exploration and result in faster convergence to the optimal policy.

Hence, our problem focuses on learning a dense reward function (denoted as $R$), which when provided as the reward signal to RL techniques results in the optimal policy for the MDP, $\mathcal{M} = (\mathcal{S}, \mathcal{A}, \mathcal{T}, R_G)$. To solve this problem, we assume access to the MDP state and action specifications, the sparse reward function $R_G$, a training environment (i.e., robot’s real or simulated environment), and (optionally) expert observation-only demonstrations, i.e., state sequences from an expert performing the task. Further, we delimit our scope to manipulation tasks where task progress is monotonic (i.e., the optimal policy does not induce cycles in the state space). In relation to RL, the two rewards $R_G$ and $R$ can be viewed as extrinsic (specified by the human designer) and intrinsic (self-supervised) reward signals of the robot, respectively [18].

III. LEARNING REWARDS FOR MULTIMODAL OBSERVATIONS

The core idea of our method is to learn a continuous variable $p \in [0, 1]$ from the observation to represent the current progress towards completing the given task. We name it the task progress variable. When $p = 0$, it indicates the robot is at the initial state and $p = 1$ indicates the task is finished. If task progress is learned for each observation, it can then be directly used as the reward for policy learning algorithms, i.e., $R(s_t) = p(s_t)$. We propose to learn the function $R(s)$, such that on a nominal task execution trajectory, the task progress variable is aligned with the temporal positions of the states observed. Namely, for any nominal task execution trajectory $\tau = [s_0, s_1, ..., s_{N-1}]$ and $s_{N-1}$ coincides with the goal state $s_G$, we have

$$t_2 - t_1 > \epsilon \rightarrow R(s_{t_2}) > R(s_{t_1})$$

where $0 \leq t_2 < t_1 \leq N - 1$ and $\epsilon > 0$. Our approach uses this insight for learning an embedding from the observation space $\mathcal{S}$ to a latent space $\mathcal{H}$, $h_{\phi}: \mathcal{S} \rightarrow \mathcal{H}$, in which the task progress can be measured as the distance between any state $s_t$ and the goal state $s_G$. Once the embedding is learned,\(^1\) Acquiring measurements of actions is challenging when collecting demonstrations from human experts [17], motivating the focus on observation-only demonstrations.

\(^1\)Acquiring measurements of actions is challenging when collecting demonstrations from human experts [17], motivating the focus on observation-only demonstrations.
A. Backward Sampling

To learn the embedding \( h_\phi \), state observations with different temporal positions are required as the training data. One straightforward solution is to collect many (tens to hundreds) of expert demonstrations and record the corresponding observations for each state. However, such data collection can be extremely time-consuming, making the adoption of our method difficult in practice. Thus, we propose a novel backward sampling process (i.e., sampling from the goal state to the feasible start region) to tackle the data generation problem. The similar idea was also explored in [19] for policy learning with increasing difficulty and [20] for learning generalizable shape descriptor for kit assembly.

Our proposed sampling process is based on the insight that for most manipulation problems the variance of goal state is much smaller than the start state. For instance, consider the peg-in-hole task where goal state corresponds to the peg being inside the hole, while the start state corresponds to the robot holding the peg in free space. For this task, the goal state is significantly more constrained than the start state (which has much larger variance), thereby making backward sampling more efficient compared to forward sampling. We demonstrate the efficacy of the backward sampling method with a single observation-only (without action annotations) expert demonstration available.

We achieve the backward sampling process by constructing a state tree, named as the task progress tree, where each node represents a state observation and the node’s depth represents its temporal position (in reverse order). A general framework to build task progress trees is detailed as follows:

1) Add goal state \( s_G \) to an empty seed set \( Q^0 \) with maximum capacity \( N \); assign the current depth \( d \) to 0.
2) For each of the state \( s_q \) in \( Q^d \), sample \( M \) random actions \( \{a_k, k = 1, 2, \ldots, M\} \) and apply each of them to \( s_q \) to get the next state observations \( \{s^{d+1}_k, k = 1, 2, \ldots, M\} \). Add the \( M \) next state observations into the tree as the children nodes of the parent node \( s_q \).
3) For each child node sampled in Step 2, compute an approximate progress measure \( f(s^{d+1}_{k|q}) \). Intuitively, the progress measure \( f(\cdot) \) indicates whether the state observation is progressing away from the goal state. It can be either task-agnostic such as measuring the information gain on the distribution of visited states [21], or task-specific such as using one or multiple observation-only expert trajectories as a reference. The latter option is adopted in our implementation and detailed below.
4) Select \( N \) samples from the \( M \cdot N \) child nodes in Step 2 as the new seed set \( Q^{d+1} \) based on the progress measure in Step 3; increment \( d \) to \( d + 1 \).
5) Repeat Steps 2-4 until the number of the states in \( Q^d \) that are in the start region is above a threshold \( N \cdot \delta \), where \( \delta \in (0, 1) \). For instance, for the peg-in-hole task, the start region is defined as the set of states with robot’s end-effector position being above a pre-defined height threshold.

As mentioned above, a single observation-only expert trajectory is used to construct the task-specific progress measure in our implementation (Step 3). Specifically, given the expert trajectory \( \xi = \{s^0_e, s^1_e, \ldots, s^{N-1}_e\} \), we simplify Steps 2-4 by setting \( N = 1 \). At depth \( d \), we assign \( Q^d \) as a single element set, containing the state closest to \( s^d_e \) (the \( d \)-th state in reversed order of the expert trajectory \( \xi \)) measured by robot’s end-effector pose difference. The obtained task progress tree, consists of state observation nodes along with their depths, equivalently, temporal positions (in reversed order). These
states and temporal positions are then used as training data to train the desired embedding $h_\phi$.

B. Multi-Modal Representation Learning

We aim to learn the embedding from multi-modal inputs that satisfy Eq. (2) using the data generated in Section III-A. Fig. 2 illustrates our representation learning model.

1) Multi-Modality Encoder: Three sources of sensory data are used as the inputs of our multi-modality encoder: RGB images from a fixed camera, RGB images from a wrist-mounted camera, and force-torque (F/T) readings from a wrist-mounted F/T sensor. We adopt a similar encoder architecture as used in [22]. For 128x128x3 RGB images, we use a 6-layer Convolutional Neural Network, followed by a fully-connected layer to transform each image to a 64 dimensional vector. For F/T readings, we take the last 8 readings from the 6-axis F/T sensor as a 8x6 time-series and perform 4-layer causal convolution [23] to transform the F/T readings into a 32 dimensional vector. The three vectors are concatenated and passed as input to a 2-layer Multi-Layer Perceptron to produce the final 128 dimensional hidden vector.

2) Multi-Modality Decoder: The decoder takes the fused hidden representation as input and tries to reconstruct the multi-modal sensor input. For reconstructing RGB images, we use 7-layer transposed convolution to upsample the hidden vector to the original 128x128x3 size. For F/T readings, we use 3-layer 1-d transpose convolution to convert the data back to 8x6 size. The loss function is defined between the original sensor input and reconstructed output. We use Sigmoid loss for RGB images and $L_2$ loss for F/T readings.

3) Task Progress Latent Representation Learning: Our goal is to obtain a latent space, where the distance measure between any state latent representation $h_\phi(s_t)$ and goal state latent representation $h_\phi(s_G)$ reflects the current task progress (reward), as shown in Eq. (2). The supervision signal comes from the original sensor input and reconstructed output. We use Sigmoid loss for RGB images and $L_2$ loss for F/T readings.

IV. Experiments

We aim to investigate two questions in the experiments. First, we examine if the learned reward realizes our insight, namely, states that are closer to the task goal should have higher rewards. This allows us to evaluate the effectiveness of our learned reward. Second, we study how the learned reward can be applied to policy learning in acquiring contact-rich manipulation skills. Our study is based on the evaluation in two common contact-rich manipulation tasks: peg-in-hole and USB insertion (shown in Fig. 3).

A. Experimental Setup

All the experiments are conducted in Isaac Gym [24], a GPU-accelerated simulator based on NVIDIA PhysX and Flex simulation backends, which provides high physics fidelity for contact-rich simulation. We defer validating our approach on real-robots to future work. The tasks are performed using a 7-DoF robotic arm modeled on the Kuka LBR IIWA robot. Three types of sensor observations are served as the input to the robot: 128x128 RGB images from a fixed camera, 128x128 RGB images from a wrist-mounted camera, and 6-axis F/T readings from a wrist-mounted F/T sensor. For the peg-in-hole task, we use a round peg with a clearance of 2.4mm. For the USB insertion task, the clearance is 1.0mm. The simulated robot is torque controlled and the

We explored other distance metrics, e.g., the Euclidean distance, using which our method also works. We empirically found policies trained with rewards using the chosen metric achieves the fastest convergence.
torque command is computed via the following control law:

$$\tau = -J^T K_D (\dot{x} - \dot{x}_{ref}),$$  \hspace{1cm} (4)$$

where $\tau$ denotes the 7-dimension joint torque, $J$ the Jacobian, and $K_D$ the gain matrix. $\dot{x}$ is the current end-effector twist, and $\dot{x}_{ref}$ is the twist command (action) computed by an RL agent or a scripted policy. The joint torques are sent to the robot at 100Hz and the policies are queried at 5Hz.

B. Implementation Details

In the backward sampling process for both tasks, we set the number of random actions $M = 500$. We randomly perturb the colors of the objects (peg & hole and USB male & USB female) in the scene to prevent overfitting to certain colors. To train the latent embedding model, we adopted the network architecture detailed in Section III-B.1. We trained the model on a Titan 2080Ti GPU for 20,000 iterations using Adam [25] with learning rate $lr = 2e^{-4}$.

C. Learned Reward Examination

In this experiment, we want to examine the rationality of the learned reward. Specifically, we want to test if the output of our reward model assigns sensible values to the visited states under various policies. To achieve this, we test our learned reward model with four different scripted policies on the peg-in-hole task listed below.

1) Imitate the expert demonstrator by directly inserting the peg into the hole (Direct Success).
2) Approach the hole with a small translation error until contact $\rightarrow$ Align the peg with the hole center $\rightarrow$ Insert the peg into the hole (Align Success).
3) Approach the hole with a small translation error until contact $\rightarrow$ Move away from the hole center while the peg is in contact with the hole $\rightarrow$ The peg loses contact with the hole (Search Fail).
4) Random policy (Random).

The results of the learned reward model on the four scripted policies are shown in Fig. 4. In Direct Success, the reward increases (approximately) linearly from 0 to 1 along with the number of timesteps in the trajectory. The reward in Align Success first increases similarly as in Direct Success, until the peg makes contact with the hole surface. Then it roughly stays the same while attempting to align with the hole center, and continues increasing to 1 when the peg is aligned and being inserted into the hole. For Search Fail, the reward behaves similarly as in Align Success at the beginning (increases and then plateaus). The reward then abruptly decreases to a small value (below 0.1). That is exactly the timestep when the peg loses contact with the hole surface (the force in z-axis rapidly changes from a large positive value to around 0). The reward of Random just fluctuates around a small value close to 0. The above observations demonstrate the interpretability of our learned reward model and its potential to provide denser supervision for policy learning.

D. RL Policy Learning with Learned Reward

The policy learning experiments aim to demonstrate the effectiveness of our learned reward, and provide a rigorous comparison with other reward design methods. While our approach to reward learning is agnostic to the RL algorithm being used, we use Soft Actor-Critic (SAC) in our evaluations [14]. DREM refers to our learned reward model introduced in Section III with all three modalities as input. We compare it with four baseline methods: Sparse represents the sparse reward, i.e., the binary success indicator at the end of episode; Engineered represents a hand-crafted reward $-\exp(\kappa ||x - x_G||_2)$, i.e., a function of the $L_2$ distance between the current robot’s end-effector pose and the target pose; VICE-RAQ represents the state-of-the-art reward learning algorithm on high-dimensional (image) input [11]; Image learned represents our reward model with only images as input. For all baseline experiments, we use RGB images as the input of the policy, while for DREM we use RGB images and force data as the input. We adopted a similar neural network in Section III-B.1 as the policy network. The experimental results are shown in Fig. 5.

It can be observed that our learned reward (DREM and Image learned) outperforms the other reward designs in both peg-in-hole and USB insertion, indicating that our proposed reward learning framework is able to learn reward functions that boosts RL training. The fact that DREM achieves faster convergence and a higher success rate than Image learned demonstrates the advantages of multimodal input (force-torque signals in our case), i.e., enabling a more efficient and robust policy. Sparse does not achieve any success within the training budget, showing difficulty of the two contact-rich tasks. Engineered performs satisfactorily at peg-in-hole but much worse at the more difficult USB insertion, as it requires a tighter fit and a strict orientation alignment. It should be noted that VICE-RAQ does not succeed at the two tasks experimented with; the success rate remains 0 after 150k training steps. We hypothesize that only using images, adversarial training is easily stuck in a local optimal as similar images got similar rewards even though they might be in different contact states. We constructed a significantly easier task by configuring the peg to be close to the hole initially (aligned right above the hole center), to
In this section, we provide a brief review of research on reward learning, with emphasis on applications in contact-rich manipulation. Rewards provide a mechanism for humans to specify tasks to robots [1]. However, reward specification is challenging and can lead to unanticipated behavior [26], [27]. Consequently, approaches to reward learning have attracted increasing attention in the last two decades [28], [29], [30], with inverse reinforcement learning (IRL) being the prominent paradigm [17]. IRL aims to recover a reward function given expert demonstrations [31], [32], [5]. However, as many rewards may explain the demonstrations equally well, additional objective criteria that help identify the correct reward have been explored [33], [6], [7], [34]. For instance, [7] utilize the principle of maximum entropy to learn the reward.

Recently, deep variants of IRL have also been developed with the goal of addressing tasks with larger state, observation, and action spaces [9], [10], [35]. For instance, Finn et al. [9] provide guided cost learning, which uses neural networks to parameterize the reward function. [10] provide a reward learning approach robust to changes in environment dynamics. These IRL techniques and others have been successfully demonstrated on a diverse set of problems, such as modeling driving behaviors [7], [36], [37], robotic manipulation [9], [38], and grasping [39]. Despite the steady success of IRL techniques, several open challenges remain. First, most techniques require hand-engineered features (or states) while efficient learning of rewards from high-dimensional observations remains difficult. Second, state-of-the-art IRL techniques utilize adversarial optimization [9], [10], [35], thereby inheriting the associated training instabilities [13]. Consequently, we seek to develop a reward learning approach that can reason over high-dimensional observations spaces without utilizing adversarial training.

There are a few related attempts along this line of research. Specifically, [40] re-framed imitation learning within the standard reinforcement learning setting using expert policy support estimation. However, they only evaluated their method on a low-dimensional state space. [41] proposed to use reward sketching provided by annotators to learn a dense model from the image input. The major drawback of their work is that their method requires many execution trajectories and the corresponding annotations, which are expensive to acquire. By contrast, in our proposed method, the data used to train the reward model is self-generated by the robot. The sampling process only takes a single execution trajectory, much cheaper than [41].

Many research efforts have been devoted in recent years to learning contact-rich manipulation skills, such as peg insertion, block packing, etc. However, most of the works use either images [42], [43], [44] or haptic feedback [45], [46], [47] as the policy input. There are only a few works that exploit image and force together. Specifically, [48] combined vision and force to learn to play Jenga. [22] proposed to learn a multi-modal representation of sensor inputs and utilize the representation for policy learning on peg insertion tasks, and the authors in [49] achieved motion generation for manipulation with multi-modal sensor feedback using manipulation graphs. However, all the previous works focus on policy learning for manipulation tasks, while our method tries to learn the reward function that can be seamlessly integrated into policy learning algorithms for manipulation. To the best of our knowledge, our work is the first attempt to learn dense rewards from multi-modal inputs.

VI. CONCLUSION AND FUTURE WORK

In summary, we propose an approach to learn dense rewards from multi-modal observations (DREM), with particular emphasis on contact-rich manipulation tasks. A novel backward sampling method is proposed to generate requisite training data through exploration, guided by a single expert demonstration. Dense rewards are learned from the high-dimensional observation space without adversarial training. We evaluate DREM on two assembly tasks and demonstrate its efficacy through comparisons with other learned and handcrafted reward functions.

Our work also motivates several future directions. For instance, currently DREM is geared towards monotonic tasks, i.e., where task progress is monotonic in the observation space. While this assumption is valid for a range of assembly tasks (due to the presence of defined start and goal states), extension of DREM to non-monotonic tasks remains of interest. Further, the experiments indicate that task-specific logical concepts (such as in-contact or losing-contact) underlie our
learned reward. Hence, another interesting direction is to formalize the problem of recovering such logical concepts from dense rewards to enable multi-task learning and consequently further improve sample efficiency.
