ABSTRACT

Aims. The goal of this work is to put constraints on the strength and structure of the magnetic field in the cluster of galaxies A2382. We investigate the relationship between magnetic field and Faraday rotation effects in the cluster, using numerical simulations as a reference for the observed polarization properties.

Methods. For this purpose we present Very Large Array observations at 20 cm and 6 cm for two polarized radio sources embedded in A2382, and we obtained detailed rotation measure images for both of them. We simulated random three-dimensional magnetic field models with different power spectra and thus produced synthetic rotation measure images. By comparing our simulations with the observed polarization properties of the radio sources, we can determine the strength and the power spectrum of intra-cluster magnetic field fluctuations that reproduce the observations best.

Results. The data are consistent with a power-law magnetic-field power spectrum with the Kolmogorov index $n=11/3$, while the outer scale of the magnetic field fluctuations is close to 35 kpc. The average magnetic field strength at the cluster centre is about $3 \mu G$ and decreases in the external region as the square root of the electron gas density. The average magnetic field strength in the central $1\text{ Mpc}^3$ is about $1 \mu G$.

Key words. galaxies: clusters: general – galaxies: clusters: individual: A2382 – magnetic fields – polarization – cosmology: large-scale structure of Universe

1. Introduction

The intra-cluster medium (ICM) in clusters of galaxies is known to possess a magnetic field, but its origin and properties are not well known. The existence of magnetic fields can be demonstrated with different methods of analysis (see e.g. the review byGovoni & Feretti 2004; Carilli & Taylor 2002, and references therein). The strongest evidence for the presence of cluster magnetic fields comes from radio observations. Magnetic fields are studied through the synchrotron emission of cluster-wide diffuse sources and from studies of the Faraday rotation of polarized radio galaxies. The magnetized plasma that is present between an observer and a radio source changes the properties of the polarized emission from the radio source. Therefore, the magnetic field strength can be determined with the help of X-ray observations of the hot gas, through the investigation of the Faraday rotation measure (RM) of radio sources located inside or behind the cluster.

The RM studies of radio galaxies in clusters have been carried out using either statistical samples (e.g. Lawler & Dennison 1982; Vallée et al. 1986; Kim et al. 1990, 1991; Clarke et al. 2001) or individual clusters. In the latter case one analyses detailed high-resolution RM images (e.g. Perley & Taylor 1991; Taylor & Perley 1993; Feretti et al. 1995, 1999; Govoni et al. 2001; Taylor et al. 2001; Eilek & Owen 2002; Pollack et al. 2005; Govoni et al. 2006). These data are usually consistent with central magnetic field strengths of a few $\mu G$, but stronger fields are found in the inner regions of relaxed cooling core clusters, and can reach values of $10-40 \mu G$ (see e.g. Taylor et al. 2002). Both for interacting and relaxed clusters, the RM distribution of radio galaxies is generally patchy, indicating that cluster magnetic fields have structures on scales as small as 10 kpc or less.

On the basis of the available RM images, increasing attention is given in the literature to the power spectrum of the intra-cluster magnetic field fluctuations. Several studies (Enßlin & Vogt 2003; Murgia et al. 2004) have shown that detailed RM images of radio galaxies can be used to infer not only the cluster magnetic field strength, but also the cluster magnetic field power spectrum. The analysis of Vogt & Enßlin (2003, 2005) suggests that the power spectrum is of the Kolmogorov type if the auto-correlation length of the magnetic field fluctuations is on the order of a few kpc. However, Murgia et al. (2004) point out that shallower magnetic field power spectra are possible if the magnetic field fluctuations extend out to several tens of kpc. Recently, Govoni et al. (2006) used the numerical approach developed by Murgia et al. (2004) to derive the power spectrum of the intra-cluster magnetic field fluctuations in A2255, and found that the field strength declines from the cluster centre outwards, with an average field strength of about $1.2 \mu G$ over the central $1\text{ Mpc}^3$. They also showed that to explain both the observed RM of the radio galaxies in A2255 and polarization levels of the radio halo present in this cluster (Govoni et al. 2005), the maximum scale of the magnetic field fluctuations must be about hundreds of kpc with a steepening of the power spectrum from the cluster centre to the periphery.

Article published by EDP Sciences
The pointing position (J2000) is at RA = 21\textdegree 51\textquoteleft 57\textquoteleft\ and Dec = −15\textdegree 37\textquoteright\ 23\textquoteright.\n
In this paper we present Very Large Array (VLA\textsuperscript{1}) observations at 20 cm and 6 cm of the three polarized radio galaxies PKS 2149-158 (A and B) and PKS 2149-158C in the cluster Abell 2382; the first two (A and B) form a dumb-bell system. A2382 is an ideal case for studying RM along different lines-of-sight because PKS 2149-158 and PKS 2149-158C are extended and highly polarized radio galaxies, located respectively at 4.8\ arcmin and 4.3\ arcmin from the cluster centre. Because the radio sources under investigation are quite extended, both in angular and linear size, they are ideal targets for an analysis of the rotation measurement distribution: detailed RM images can be constructed that can serve as the basis of an accurate study of magnetic field power spectra.

We follow the numerical approach proposed by Murgia et al. (2004); i.e. we study the polarization properties of the radio galaxies, at the same time making use of the cluster X-ray information.

The paper is organised as follows. In Sect. 2 we discuss details about the radio observations and the data reduction. In Sect. 3 we present the total intensity and polarization properties of the radio galaxies at 20 and 6 cm. We also describe the morphology of the sources and the discrete features found in the total intensity images. In Sect. 4 we present the X-ray environment in which the radio galaxies are embedded. In Sect. 5 we show the RM images, discuss the results, and discuss the cluster magnetic field. In Sect. 6 we introduce the multi-scale magnetic field modelling used to determine the intra-cluster magnetic field strength and structure, and we show the results obtained with different configurations of the magnetic field power spectrum slope. Finally, Sect. 7 summarises our main conclusions.

Throughout this paper we assume a $\Lambda$CDM cosmology with $H_0 = 71$ km s\textsuperscript{−1} Mpc\textsuperscript{−1}, $\Omega_\text{m} = 0.3$, and $\Omega_\Lambda = 0.7$. At the distance of A2382 ($z = 0.0618$, Struble & Rood 1999), 1 arcsec corresponds to 1.17 kpc.

2. Radio observations and data reduction

The radio sources PKS 2149-158 (A and B) and PKS 2149-158C were observed at the 20 and 6 cm bands, in all VLA configurations. The details of the observations are provided in Table 1. The observations in the different arrays were made between November 1986 and December 1987.

The flux densities were brought on the scale of Baars et al. (1990) using 3C 286 as the primary flux density calibrator. The same calibrator was used as the absolute reference for the electric vector polarization angle. The phase calibrators were nearby point sources observed at intervals of about 30 min.

Calibration and imaging were performed with the NRAO Astronomical Image Processing System (AIPS), following standard procedures. Several cycles of self-calibration and CLEAN were applied to remove residual phase variations. Instrumental calibration of the polarization leakage terms was obtained using the phase calibrators, which were observed over a wide range in parallactic angle. The calibration of the absolute polarization angle was obtained by assuming an R-L phase difference of 66\degree for the source 3C 286 at both 20 and 6 cm.

The (u, v) data at the same frequencies but from different configurations were first handled separately and then combined to improve uv-coverage and sensitivity. The separate data sets were individually flagged, flux calibrated, and polarization-calibrated before combination. We combined all arrays at both 20 cm and 6 cm. Each combined data set was then self-calibrated.

Images of polarized intensity $P = (Q^2 + U^2)^{1/2}$, fractional polarization $FPOL = P/I$, and position angle of polarization $\Psi = 0.5 \tan^{-1}(U/Q)$ were derived from the $I$, $Q$, and $U$ images.

3. Total intensity and polarization properties

Radio images at 20 cm and 6 cm were obtained by combining all the VLA arrays and by averaging the two IFs. The left panel of Fig. 1 shows the total intensity contours of the 20 cm image, which was restored with an FWHM beam of 5.3\ arcmin, overlaid onto the optical image\textsuperscript{2} from the red Palomar Digitized Sky Survey 2. A zoom over the dumb-bell system is presented in the right panel of Fig. 1, where we show the total intensity contours of the 6 cm image, which was restored with an FWHM beam of 0.4\×\ 0.5\ arcmin.

The basic properties of PKS 2149-158 and PKS 2149-158C are given in Table 2. Flux densities were estimated, after having applied the primary beam correction, by integrating in the same area the surface brightness down to the noise level.

For the purpose of the polarization and RM analysis, intensity and polarization images were also produced for each IF separately. The relevant information on these images is listed in Table 3. Total intensity contours and polarization vectors at 1.46 GHz and 4.88 GHz are shown in Figs. 2 and 3, respectively. Vectors represent the orientation of the projected E-field and are proportional in length to the fractional polarization. In the fractional polarization images $FPOL$, we only included the points with $I > 5\sigma_I$.

In the following we give a brief description of the individual sources.

3.1. PKS 2149-158 (A and B)

PKS 2149-158 (FR class I) is a double system composed of two nearly equally bright elliptical galaxies in a common envelope ("dumb-bell" galaxy). The radio source was first mapped by Parma et al. (1991) at 1.4 GHz. Both galaxies of the dumb-bell system are radio-emitters, forming a double twin jet system like 3C 75 (Owen et al. 1985). The two radio cores, labelled A and B in Fig. 1, are separated in projection by 13.5\ arcmin which corresponds to 15.8 kpc. Their position is reported in Table 2.

The radio morphology of PKS 2149-158, which shows regular large amplitude oscillations, is rather unusual and can be interpreted in terms of two distinct radio sources whose jets are strongly interacting. The true (three-dimensional) source structure is undoubtedly even more complex, because the radio jets

| Total radio luminosity at 20 cm              | 1.2×10²⁶ W/Hz  | 1.0×10²⁶ W/Hz  |
| Overall spectral index α²⁰cm                  | 0.95          | 0.86           |
| Radio source largest linear size             | 410 kpc       | 210 kpc        |

We use the convention S, = ν⁻α.

The magnetic field configuration, as traced by the 6 cm images, is initially transverse to the jets, parallel to the southern lobe, and circumferential in the northern lobe. The mean fractional polarization is 7% at 20 cm and 25% at 6 cm. As for the dumb-bell system, the signal is affected by beam depolarization at a longer wavelength.

4. X-ray environment

The cluster A2382 was observed in X-rays with the Rosat satellite. The left panel of Fig. 4 shows total intensity contours at 6 cm superposed on the ROSAT PSPC archive image (800227p) of A2382. The X-ray image represents intensity in the 0.1–2.4 keV band. It has been corrected for the background, divided by the exposure map (a ≃17 ks exposure) and smoothed with a Gaussian of σ = 30''. The centroid of the image is located at RA = 21°51'55''55'' Dec = -15°42'26''. The X-ray emission extends up to more than 15''. The radio-X overlay shows that the two radio sources PKS 2149-158 and PKS 2149-158C are offset to the north of the cluster centre by about 4.8' (340 kpc) and 4.3' (300 kpc), respectively.

4.1. X-ray surface brightness profile

The right panel of Fig. 4 shows the X-ray surface brightness (S_X) profile of A2382. The profile was obtained by averaging the 0.1–2.4 keV Rosat image (corrected for the background and divided by the exposure) in concentric annuli of 30'' in size, centred on the X-ray centroid. Point sources have been masked. We converted the X-ray surface brightness from counts/skypixel/s to erg cm⁻² s⁻¹ sterad⁻¹ by using the PIMMS³ software (Mukai 2007). In this conversion the X-ray emission was approximated by a Raymond-Smith model with a mean cluster temperature ³http://heasarc.gsfc.nasa.gov/docs/software/tools/pimms.html
Table 3. Total and polarization intensity radio images, for each individual IF, restored with a FWHM beam of $5.3'' \times 5.3''$.

|         | 1.667       | "          | 0.047                | 0.027                 | 0.027                |
|         | 4.83        | "          | 0.022                | 0.019                 | 0.019                |
|         | 4.88        | "          | 0.020                | 0.019                 | 0.019                |

Fig. 2. Source PKS 2149-158 (A and B) and PKS 2149-158C: total intensity contours and polarization vectors at 1.46 GHz. The angular resolution is $5.3'' \times 5.3''$. The first contour level is drawn at $-3\sigma_I$ and the other contour levels start at $3\sigma_I$ and are spaced by a factor of 2. The lines give the orientation of the electric vector position angle (E-field) and are proportional in length to the fractional polarization ($10^\% \approx 50\%$).

$kT \approx 2.9$ keV (Ebeling et al. 1996), metal solar abundance $Z = 0.6$, and photoelectric absorption column density of $nH = 4.1 \times 10^{20}$ cm$^{-2}$.

Because a strong emission core is present in the inner 100 kpc of the cluster, the observed $S_X$ cannot be described by the simple $\beta$-model (Cavaliere & Fusco-Fermiano 1976) for the gas density:

$$n_e(r) = n_0(1 + r^2/r_c^2)^{-\frac{\beta}{2}},$$  \hspace{1cm} (1)

where $r$, $n_0$, and $r_c$ are the distance from the cluster X-ray centroid, the central electron density, and the cluster core radius, respectively.

Therefore, we first fitted the radial X-ray surface brightness only for $r > 100$ kpc using the $\beta$-model with the three free parameters $\beta_{\text{EXT}}$, $r_{\text{cEXT}}$, $n_{0\text{EXT}}$, resulting in a best fit with $\chi^2_{\text{EXT}} = 11.8$, for 16 degrees of freedom. We then used these values in a subsequent fit of the $S_X$ profile by combining a double $\beta$-model:

$$n_e(r) = n_{0\text{INT}}(1 + r^2/r_c^2)^{-\frac{\beta_{\text{INT}}}{2}} + n_{0\text{EXT}}(1 + r^2/r_{\text{cEXT}}^2)^{-\frac{\beta_{\text{EXT}}}{2}}.$$  \hspace{1cm} (2)

The double $\beta$-model is based on 6 parameters ($\beta_{\text{INT}}$, $r_{\text{cINT}}$, $n_{0\text{INT}}$, $\beta_{\text{EXT}}$, $r_{\text{cEXT}}$, $n_{0\text{EXT}}$), of which the last three are fixed at the values calculated by the previous fit. In this case, the final $\chi^2_{\text{INT}}$ is 15.0 for 19 degrees of freedom. The fits of the two $\beta$-models (single and double) are shown respectively in Fig. 4 (right panel). The best fit parameters are listed in Table 4. Overall the model fit is very good. It gives a central gas density of $n_0 \equiv n_{0\text{INT}} + n_{0\text{EXT}} = 5 \times 10^{-3}$ cm$^{-3}$ and a outer core radius of 373 kpc with a outer $\beta_{\text{EXT}}$ of 0.9. The inner $\beta_{\text{INT}} > 0.7$ and $r_{\text{cINT}} > 11$ kpc are lower limits. This means that higher and higher values of the inner core radius and $\beta$ still satisfy the data, provided that these two parameters grow together.

5. Rotation measure images

Polarized radiation from cluster and background radio galaxies may be rotated by the Faraday effect if magnetic fields are present in the intra-cluster medium. Linearly polarized electromagnetic radiation passing through a magnetized ionized medium suffers a rotation of the plane of polarization,

$$\Psi_{\text{Obs}}(\lambda) = \Psi_{\text{INT}} + (\lambda/\lambda_0)^2 \times \text{RM},$$  \hspace{1cm} (3)

where $\Psi_{\text{Obs}}(\lambda)$ is the position angle observed at a wavelength $\lambda$, $\Psi_{\text{INT}}$ the intrinsic position angle. The rotation measure (RM) is related to the electron density ($n_e$), the magnetic field along the
The position angle of the plane of polarization is an observable quantity; therefore, images of rotation measure can be obtained by a linear fit of the polarization angle as a function of $\lambda^2$ (see e.g. AIPS task RM or the PACERMAN algorithm by Dolag et al. 2005). As is well known, determination of the rotation measure is complicated because of $n\pi$ ambiguities in the observed $\Psi_{\text{obs}}$. Removal of these ambiguities requires observations at many frequencies that are well-spaced in $\lambda^2$.

We implemented an RM-fit algorithm in the FARADAY tool (Murgia et al. 2004). Given the $U$ and $Q$ maps at each frequency as inputs, the task $UQ\_to\_RM$ produces the RM and the intrinsic line-of-sight ($B_\parallel$), and the path-length ($L$) through the intracluster medium according to:

$$\text{RM}_{[\text{rad}/\text{m}^2]} = 812 \int n_e [\text{cm}^{-3}] B_\parallel [\mu\text{G}] dl. \quad (4)$$

The position angle of the plane of polarization is an observable quantity; therefore, images of rotation measure can be obtained by a linear fit of the polarization angle as a function of $\lambda^2$ (see e.g. AIPS task RM or the PACERMAN algorithm by Dolag et al. 2005). As is well known, determination of the rotation measure is complicated because of $n\pi$ ambiguities in the observed $\Psi_{\text{obs}}$. Removal of these ambiguities requires observations at many frequencies that are well-spaced in $\lambda^2$.

We implemented an RM-fit algorithm in the FARADAY tool (Murgia et al. 2004). Given the $U$ and $Q$ maps at each frequency as inputs, the task $UQ\_to\_RM$ produces the RM and the intrinsic line-of-sight ($B_\parallel$), and the path-length ($L$) through the intracluster medium according to:

$$\text{RM}_{[\text{rad}/\text{m}^2]} = 812 \int n_e [\text{cm}^{-3}] B_\parallel [\mu\text{G}] dl. \quad (4)$$

The position angle of the plane of polarization is an observable quantity; therefore, images of rotation measure can be obtained by a linear fit of the polarization angle as a function of $\lambda^2$ (see e.g. AIPS task RM or the PACERMAN algorithm by Dolag et al. 2005). As is well known, determination of the rotation measure is complicated because of $n\pi$ ambiguities in the observed $\Psi_{\text{obs}}$. Removal of these ambiguities requires observations at many frequencies that are well-spaced in $\lambda^2$.
polarization angle, both with relative error maps, and a $\chi^2$ map, obtained by fitting the observed polarization angle images. To improve the RM image, the algorithm can be iterated several times, by using the RM information in the high signal-to-noise region and thus improving computations in adjacent bad pixels.

Figure 5 shows the image of the rotation measure of PKS 2149-158 and PKS 2149-158C computed using the polarization Q and U maps at the frequencies 1.46, 1.66, 4.83, and 4.88 GHz with a resolution of $5''$.3. Contours refer to the total intensity image at 6 cm. The RM was calculated only in pixels with $f > 3\nu$ at 6 cm. In the RM image thus obtained, we blanked all pixels with a fitting error greater than 10 rad/m$^2$. The bulk of the RM values range from about $-100$ rad/m$^2$ up to 100 rad/m$^2$. Alternating positive and negative RM patches are apparent in each source with RM fluctuations down to scales of a few kpc.

In order to quantify the goodness of the fit of the rotation measure image, we show the RM error image and the $\chi^2$ map in Fig. 6. The average error of the RM as given by the fit procedure is about 5 rad/m$^2$, while the average reduced $\chi^2$ is 1.4.

We can characterise the RM distribution in terms of a mean ($\langle \text{RM} \rangle$) and root mean square ($\sigma_{\text{RM}}$). Figure 7 shows the histograms of the RM distribution for the two sources. The distributions of RM have approximately zero mean; in detail: for PKS 2149-158, we found $\langle \text{RM} \rangle = 0.8$ rad/m$^2$ and $\sigma_{\text{RM}} = 31$ rad/m$^2$, while for PKS 2149-158C ($\langle \text{RM} \rangle = -4.2$ rad/m$^2$ and $\sigma_{\text{RM}} = 46$ rad/m$^2$.

To verify the polarization angle linearity with $\lambda^2$, in the RM map we selected some pixels corresponding to source regions with high and low RM and $\chi^2$ values. Figure 8 shows the fits computed in such positions, indicated in the inserted image. The data are represented well by a linear $\lambda^2$ relation. These results agree with the interpretation that external Faraday rotation is the dominant mechanism in the sources, although a much wider $\lambda^2$ range, measured with a finer sampling, would be needed to confirm this hypothesis unambiguously.

Table 5 reports, for the two sources (both separate and together), the (RM) the $\sigma_{\text{RM}}$ and the maximum ($\text{RM}_{\text{max}}$) absolute value of the RM distribution. These data were not corrected for the Galactic contribution, which is probably negligible. In fact, in galactic coordinates $A2382$ is located at lon $= 38.91'$ and lat $= -46.93'$ and based on the average RM for extragalactic sources published by Simard-Normandin et al. (1981), the RM Galactic contribution in a region of about $10^\circ$ centred on $A2382$ is expected to be about $-5$ rad/m$^2$. The RM results are consistent with the interpretation that the external Faraday screen is mostly due to the intracluster medium, indeed the source located in projection nearest to the cluster centre, i.e. PKS 2149-158C, also has a higher RM.

The RM structures on small scales can be explained by the fact that the cluster magnetic field fluctuates on scales smaller than the size of the sources. These results suggest that it is necessary to consider a cluster magnetic field that fluctuates over a wide range of spatial scales.

### 6. RM analysis: characterization of the intracluster magnetic field power spectrum

The software package FARADAY (Murgia et al. 2004) permits the study of cluster magnetic fields by comparing the observed RM with simulated RM images obtained by considering three-dimensional multi-scale cluster magnetic field models. In fact, given a three-dimensional magnetic field model and the density distribution of the intra-cluster gas, FARADAY calculates the expected RM image by integrating Eq. (4) numerically. In the specific case of $A2382$, the integration is performed from the cluster centre up to three core radii (~1.1 Mpc) along the line-of-sight; i.e. both sources are supposed to lie in a plane that is perpendicular to line-of-sight and intercepts the cluster centre. In the following we neglect the three-dimensional structure of the radio sources and assume that all the Faraday rotation occurs in the intracluster medium in between us and the sources.

The software has been adapted in such a way that it is now possible to treat the simulations in the same way as the observations, i.e., using the same fit procedure as used to derive the observed RM. In particular, by using a source model of the intrinsic fractional polarization, polarization angle, and the observed $I$, $U$, and $Q$ images, the task $\text{RM}_\text{to UQ}$ produces, at each frequency and with the same noise as the data, the expected $Q$ and $U$ images corresponding to the simulated RM. Furthermore, we can take both the beam and bandwidth depolarization effects into account. The synthetic $U$ and $Q$ images can then be processed by the task $\text{UQ}_\text{to RM}$, resulting in final simulated RM images that are filtered with the same algorithm as the observations. In this way, the properties of the noise in the simulated RM images are very close to those of the data. In particular, non-linear effects produced by the fit procedure, such as those due to the $nr$-ambiguities, are included in the simulations as well.

#### 6.1. The magnetic field model

We considered the power spectrum of the cluster magnetic field to be a power law of the type

$$|B_k|^2 \propto k^{-\alpha}$$

(5)

in a three-dimensional cubical box. The simulations begin in the Fourier space by extracting the amplitude of the magnetic field fluctuations from a Rayleigh distribution whose standard deviation varies with the wave number according to Eq. (5). The phase of the magnetic field fluctuations is random. We then performed a three-dimensional Fast Fourier Transform (FFT) inversion to produce the magnetic field in the real space domain. The field is Gaussian and isotropic, in the sense that there is no privileged direction in space for the magnetic field fluctuations. We used a grid size of 1024 pixels in size in the wave number (Fourier) domain, which allows us to study the magnetic field fluctuations over a range of spatial scales more than two orders of magnitude wide.

Note that throughout this paper the power spectra are expressed as vectorial forms in $k$-space. The one-dimensional forms can be obtained by respectively multiplying by $4\pi k^2$ and $2\pi k$ the three and two-dimensional power spectra. According to this notation, the Kolmogorov spectral index is $n = 11/3$.

Here we refer to the length $\Lambda$ as the magnetic field reversal scale. In this way, $\Lambda$ corresponds to a half-wavelength, i.e. $\Lambda = 0.5 \cdot (2\pi/k)$. 

---

Column 1: source; Col. 2: projected distance from the X-ray centroid; Col. 3: mean of the RM distribution; Col. 4: rms of the RM distribution; Col. 5: maximum absolute value of the RM distribution.

In this set of simulations, the slope and the range of spatial scales of the magnetic field fluctuation is the same all over the cluster volume. However, the normalization of the power spectrum decreases with the distance from the cluster centre. In particular, the average magnetic field strength varies according to

$$\langle B(r) \rangle = \langle B_0 \rangle \left[ \frac{n_e(r)}{n_0} \right]^n$$

(6)

where $\langle B_0 \rangle$ is the average magnetic field strength at the cluster centre, while $n_e(r)$ is the thermal electron gas density assumed to follow the double $\beta$-model profile described in Sect. 4.1. The adopted magnetic field model has five free parameters (see Table 6): $B_0$, $n$, $\Lambda_{min}$, $\Lambda_{max}$, and $\eta$.

By varying all these parameters we obtain synthetic RM images characterised by very different statistics and structures. Our purpose is to find the combination of model parameters that gives the best representation of the observed distribution of $\sigma_{RM}$ and $\langle RM \rangle$ across the sources, as well as their RM auto-correlation function.

Ideally, one would like to fit all the five free parameters simultaneously. However, in our case this is not very practical, because of the computational burden caused by the FFT inversion. Therefore we performed a series of simulations that search the best magnetic field power spectrum by varying at most one or two parameters at a time, while keeping the others fixed. We found that there are two main degeneracies between the model parameters. The first one is between $n$ and $\Lambda_{max}$: the higher $n$, the lower $\Lambda_{max}$. The second one is between $\eta$ and $B_0$: the higher $\eta$, the higher $B_0$. This means that different combinations of these parameters may yield an equally good fit to the data.

In Sect. 6.2 we show the results obtained first by fixing $\Lambda_{min}$ and $\Lambda_{max}$ while varying $n$. Then we give the results obtained by fixing the spectral index at the Kolmogorov value ($n = 11/3$) while varying $\Lambda_{max}$. In both cases we considered $\Lambda_{min} = 6$ kpc and $\eta = 0.5$. The choice for $\eta$ is justified in Sect. 6.3, where we also analyse how the $\eta$ parameter affects the magnetic field strength. The choice for $\Lambda_{min}$ is supported by observations that
Fig. 6. Left: RM error image. Right: $\chi^2$-reduced map of the fit computed to obtain RM image. Contours refer to the total intensity image at 6 cm. The sensitivity (1$\sigma$) is 0.015 mJy/beam; the contour levels start at 3$\sigma$ and are scaled by a factor of 2.

Fig. 7. Histograms of the rotation measure images of PKS 2149-158 (left) and PKS 2148-158C (right).

reveal RM fluctuations on small scales. However, in Sect. 6.4 we analyse the effect of the magnetic field minimum scale on the polarization properties of the observed radio galaxies.

6.2. RM statistics and auto-correlation function

In the following we compare the simulated and observed RM images. To assess whether a given magnetic field power spectrum is able to reproduce the data, we considered two approaches: i) we analysed the RM statistics ($\sigma_{RM}$ and $\langle RM \rangle$) calculated over areas of increasing size, and ii) we compared the RM auto-correlation functions.

To calculate the RM statistics, we covered the RM images with a regular grid of boxes of a given size. We then calculated a global average of all the $\sigma_{RM}$ and $\langle RM \rangle$ values found in each box. By changing the size of the boxes in the grid we obtained a trend of the average $\sigma_{RM}$ and $\langle RM \rangle$ as a function of the box size. We varied the size of the boxes from a minimum size of 15 kpc (49 boxes) up to a maximum size of 300 kpc (1 box).

The RM auto-correlation function is calculated as

$$A(r) = \langle RM(x, y) \cdot RM(x + dx, y + dy) \rangle$$

where $r = \sqrt{dx^2 + dy^2}$, while the average is taken over all the positions $(x, y)$ in the RM images, excluding blanked pixels. It is worth mentioning that $A(0) = \langle RM^2 \rangle = \sigma_{RM}^2 + \langle RM \rangle^2$.

In Fig. 9 we show the results of a set of simulations obtained by fixing $\eta = 0.5$, $\Lambda_{min} = 6$ kpc, $\Lambda_{max} = 128$ kpc, and by varying $B_0$ for three different values of $n = 1, 2, 3$. The choice of $\eta$ and $\Lambda_{min}$ is discussed in Sects. 6.3 and 6.4, respectively. The value of $\Lambda_{max}$ has been arbitrarily fixed at 128 kpc. This choice is motivated by the evidence of a zero $\langle RM \rangle$ in both radio galaxies, which indicates that the largest scales of the magnetic field fluctuations are smaller than the source size. In the top and middle panels of Fig. 9 we present the observed and the simulated RM images, using the same colour scale, cellsize and resolution. In the bottom left and right panels, we show the RM statistics and the RM auto-correlation functions, respectively.

The global $\sigma_{RM}$ calculated over sources is our most reliable statistical indicator, since it is based on a large number of
independent measurements. Thus, in the fit procedure we first attempt to reproduce the \( \sigma_{\text{RM}} \) of the largest box in the statistics (the 300 kpc dot) by adjusting \( \langle B_0 \rangle \) for the three power spectra. We obtained a good fit of the \( \sigma_{\text{RM}} \) trend for all values of \( n \) with a central magnetic field strength \( \langle B_0 \rangle \) in the range 3.2–4.7 \( \mu \text{G} \). However, it is clear that \( n = 3 \), where most of the power of the RM fluctuations are concentrated on \( \Lambda_{\text{max}} \), results in an (RM) level that is much higher than observed, while \( n = 1 \), where the strongest RM fluctuations are on \( \Lambda_{\min} \), generates an (RM) lower than observed. The analysis of the (RM) trend suggests that if \( \Lambda_{\max} = 128 \text{ kpc} \) the power spectrum spectral index should be close to \( n = 2 \). This is quantitatively confirmed by the values of the reduced \( \chi^2 \) reported in the bottom left panel of Fig. 9. Following Govoni et al. (2006), the \( \chi^2 \) has been calculated according to

\[
\chi^2 = \sum \frac{[|\langle \text{RM}_{\text{obs}} \rangle| - |\langle \text{RM}_{\text{sim}} \rangle|]^2}{\text{err}^2_{\text{RM}_{\text{obs}}} + \text{err}^2_{\text{RM}_{\text{sim}}}}
\]

(8)

where the errors in the denominator take the statistical uncertainties into account in the data, as well as in the simulations\(^6\).

The same behaviour is seen in the RM auto-correlation functions shown in the bottom right panel of Fig. 9. A magnetic field power spectrum characterised by a spectral index \( n = 3 \) and \( \Lambda_{\max} = 128 \text{ kpc} \) has too much power on all scales compared to the data. On the other hand, a magnetic field power spectrum characterised by a spectral index \( n = 1 \) generates an RM image whose auto-correlation function lies below the observed one over most of the considered range of scales. The RM auto-correlation function corresponding to the intermediate case \( n = 2 \) gives a better description of the data, confirming the result found with the RM statistics.

Even if the data can be quite explained fully by a flat (\( n = 2 \)) and a broad (\( \Lambda = 6–128 \text{ kpc} \)) magnetic field power spectrum, because of the degeneracy existing between \( n \) and \( \Lambda_{\max} \), the observed RM can also be explained by a narrower and steeper power spectrum. We produced a second set of simulations in which we kept the slope of the power spectrum fixed at the Kolmogorov value, \( n = 11/3 \), and let \( \langle B_0 \rangle \) vary for three different values of \( \Lambda_{\max} = 25, 35, 50 \text{ kpc} \). The values of \( \eta \) and \( \Lambda_{\min} \) are the same as in the previous set of simulations.

In Fig. 10 we compare the observed and simulated RM images corresponding to \( n = 11/3 \). We found that \( \langle B_0 \rangle \) falls in the range 2.7–4.6 \( \mu \text{G} \), a result that is very close to what was found previously. However in this case the degree of similarity between the simulated and the observed RM images is remarkable. As can be seen in the bottom panel of Fig. 10, the Kolmogorov models reproduce the data better than the wider and flatter power spectra considered above. In particular, the magnetic field power spectrum characterised by \( n = 11/3 \) and \( \Lambda_{\max} = 35 \text{ kpc} \) provides an excellent fit to the observed (RM) profile, yielding a reduced \( \chi^2 \) close to unity. The Kolmogorov model with \( \Lambda_{\max} = 25 \text{ kpc} \) does not have enough power on large scales to reproduce the observed (RM) levels. The model with \( n = 11/3 \) and \( \Lambda_{\max} = 50 \text{ kpc} \) provides a good fit to the (RM) statistics but fails to reproduce the observed \( \sigma_{\text{RM}} \) values on scales below 20 kpc.
This is further confirmed by the analysis of the RM auto-correlation functions shown in the right panel of Fig. 10. The RM auto-correlation function of the Kolmogorov power spectrum with $\Lambda_{\text{max}} = 35$ kpc is very similar to the observed one. The Kolmogorov power spectrum with $\Lambda_{\text{max}} = 25$ kpc has too much power on small scales, and its auto-correlation function cuts off faster than the observed one. The model with $\Lambda_{\text{max}} = 50$ kpc has too much power below 20 kpc and cuts off too late in terms of...
spatial scales, thus failing to reproduce the observed RM auto-correlation function.

To summarise, the analysis of the RM statistics and auto-correlation functions reveals that the best fit to the data is obtained by a Kolmogorov power spectrum with $\Lambda_{\text{max}} = 35$ kpc and $\langle B_0 \rangle = 3.3 \mu$G.
6.3. The magnetic field strength radial profile

The amount of RM depends on the integral of the product of the field intensity and the electron density along the line-of-sight (see Eq. (4)). This dependency results in a degeneracy between the \( \eta \) and \( B_0 \) parameters. Although \( \eta \) does not dramatically affect the estimate of the magnetic field power spectrum spectral index, it can however strongly affect the estimate of the magnetic field strength. In particular, the steeper the magnetic field radial trend, i.e. the higher \( \eta \), the higher \( \langle B_0 \rangle \) should be in order to reproduce the observed RM levels. Here we justify the choice \( \eta = 0.5 \) adopted in Sect. 6.2, and we critically discuss the estimate of the magnetic field central strength as a function of the \( \eta \) parameter. It is possible to obtain a constraint on the index \( \eta \), thereby allowing measurement of the magnetic field strength in A2382, by comparing the observed and simulated \( \sigma_{\text{RM}} \) profile as a function of distance from the cluster centre.

In Fig. 11 we show the observed \( \sigma_{\text{RM}} \) profile compared with the simulations obtained for different values of the \( \eta \) parameter for the model that best reproduces the observed RM image statistics and auto-correlation function, i.e. \( n = 11/3 \), \( \Lambda_{\min} = 6 \) kpc, and \( \Lambda_{\max} = 35 \) kpc. The radial profiles shown in Fig. 11 have been traced by calculating \( \sigma_{\text{RM}} \) in 50 kpc wide concentric annuli centred on the cluster X-ray centroid. The simulated radial profiles were extended to both smaller and larger distances from the centre compared to the range of distances covered by PKS 2149-158 and PKS 2148-158C. For this reason, and unlike the procedure described in Sect. 6.2, the simulated RM images were not filtered in the same way as the observed images. Instead, we added a constant RM noise of 15 rad m\(^{-2}\) in quadrature to the simulated \( \sigma_{\text{RM}} \). This value is the average noise introduced by the fit procedure in the case of the considered magnetic field model.

The analysis of the radially average \( \sigma_{\text{RM}} \) profiles presented in Fig. 11 shows that the best fit of the data is obtained with \( \eta = 0.5 \) and \( \langle B_0 \rangle = 3.6 \) \( \mu \)G. This value of \( \eta \) corresponds to a magnetic field whose energy density decreases from the cluster centre as the square root of the gas electron density. The value of the central magnetic field strength obtained through the fit of the radially averaged \( \sigma_{\text{RM}} \) profile is indeed in very good agreement with the value obtained by the fit of the RM statistics, \( \langle B_0 \rangle = 3.3 \) \( \mu \)G. A constant magnetic field, represented by the \( \eta = 0 \) profile with a strength of \( \langle B_0 \rangle = 0.9 \) \( \mu \)G, also provides a good fit of the data, although the \( \chi^2 \) is slightly worse than the case corresponding to \( \eta = 0.5 \). The steepest magnetic field radial profile considered here, \( \eta = 1 \), provides the highest central magnetic field strength \( \langle B_0 \rangle = 13 \) \( \mu \)G but also the worst fit of the data. The formal uncertainty in the central magnetic field as provided by the fit procedure, i.e. excluding all the systematic effects and by keeping fixed all the other four parameters, is approximately \( \langle B_0 \rangle = 3.6 \pm 0.5 \mu \)G. However, Fig. 11 shows that, if we allow both \( \eta \) and \( \langle B_0 \rangle \) to vary, the 1-\( \sigma \) confidence region around the best-fit parameters is certainly larger, and a safer estimate is to consider the central magnetic field strength in the range \( 1 < \langle B_0 \rangle < 13 \mu \)G.

It should be noted that the above conclusions are based on the assumption that PKS 2149-158 and PKS 2148-158C lie at the same distance along the line-of-sight. On the other hand, even if different values of the \( \eta \) parameter lead to quite different values for the central magnetic field strength, the average magnetic field strength over a larger cluster volume is nearly the same for the three indices \( \eta \). In fact, the average magnetic field strength over the central 1 Mpc\(^3\) is almost the same for all three models: \( \langle B \rangle_{1 \text{Mpc}^3} = 1 \mu \)G.

6.4. The depolarization constraint on the magnetic field minimum scale

In all the models considered so far, we fixed the value of the minimum scale of magnetic field fluctuations to \( \Lambda_{\min} = 6 \) kpc. This choice was motivated by the fact that this scale matches the linear resolution of the radio images, i.e. 6.2 \( \times \) 6.2 kpc. Here we evaluate the effects on the simulated RM images by
considering a $\Lambda_{\text{min}}$ that is smaller than the beam. The size of the computational box allows us to push the value of $\Lambda_{\text{min}}$ down to 1 kpc. The most direct consequence arising from a magnetic field power spectrum that fluctuates on smaller scale than the linear resolution of the observations is the beam depolarization effects. With the same FARADAY tool as used to filter the simulations, as well as the observations, it is possible to translate an RM image into $U$ and $Q$ images at any given frequency and resolution. This allows us to estimate the amount of beam depolarization resulting from different values of $\Lambda_{\text{min}}$. In Fig. 12 we show the comparison of the observed and simulated fractional polarization in the case of the best-fit magnetic field model with $n = 11/3$, $\eta = 0.5$, and $\Lambda_{\text{max}} = 35$ kpc. The middle and bottom panels of Fig. 12 show the simulated fractional polarization for $\Lambda_{\text{min}} = 6$ and 1 kpc, respectively. The amount of depolarization between 4.88 and 1.46 GHz is not only in good agreement

Fig. 12. Observed and simulated depolarization for the Kolmogorov power spectrum. The fractional polarization averages comprise both the sources.
with the data, but also almost the same for the two scales. In the case of the Kolmogorov spectrum, the beam depolarization is therefore very weak. This can be explained by the fact that, for such a steep spectrum model, most of the magnetic energy density resides in the large-scale fluctuations. Thus, the simulated RM images are almost insensitive to changes in $\Lambda_{\text{min}}$. However, for the same reason we cannot put a lower limit on it. It should be considered that lowering $\Lambda_{\text{min}}$ results in a higher magnetic field strength. In the case of the Kolmogorov spectrum with $n = 11/3$, $\eta = 0.5$, and $\Lambda_{\text{max}} = 35$ kpc, by lowering $\Lambda_{\text{min}}$ from 6 to 1 kpc requires an increase in the magnetic field strength from $\langle B_0 \rangle = 3$ to 5 $\mu$G on order to explain the observed RM values. This is due to the fact that the magnetic field auto-correlation length, $\Lambda_{Bz}$, is also smaller; and since the RM scales as $\langle \text{RM}^2 \rangle \propto \langle B_0 \rangle \cdot \Lambda_{Bz}^{1/2}$ (see Eq. (15) in Murgia et al. 2004), we need to increase $\langle B_0 \rangle$ if $\Lambda_{Bz}$ is lowered.

The same considerations apply to the model with $n = 3$ and $n = 2$. The situation is different for $n = 1$. In this case most of the power of the RM fluctuation is concentrated in the small scales. Therefore, lowering $\Lambda_{\text{min}}$ leads to a significant beam
depolarization. This is illustrated in Fig. 13, where we report the simulated fractional polarization in the case of the shallow power spectrum with $n = 1$, $\eta = 0.5$, and $A_{\text{max}} = 128$ kpc. The expected fractional polarization at 1.46 GHz decreases from about 11% down to 8% when lowering $A_{\text{min}}$ from 6 to 1 kpc. Thus for a flat power spectrum with $n \leq 2$, $A_{\text{min}}$ should not be smaller than the linear resolution of the observations to prevent the depolarization of the signal at low frequencies.

### 7. Summary and Conclusions

In this work we have studied the strength and structure of the magnetic field in the cluster of galaxies A2382. Following a numerical approach, we investigated the relationship between magnetic field and Faraday rotation effects in this cluster. For this purpose, we presented Very Large Array observations at 20 cm and 6 cm of two polarized radio sources embedded in A2382, and we obtained detailed rotation measure images for both of them. We analysed the X-ray emission of A2382 observed by the ROSAT satellite and derived the radial profile of the electron gas density. The observed X-ray surface brightness profile cannot be described by a simple $\beta$-model due to the presence of a core of strong emission in the inner 100 kpc of the cluster. A double $\beta$-model provides a better fit of the X-ray surface brightness profile. There is indeed the possibility that A2382 is a cooling core cluster, although new spectroscopic X-ray observations are required in order to confirm this hypothesis.

We simulated random three-dimensional magnetic field models with different power spectra and produced synthetic RM images. We filtered the synthetic RM images with the same fit procedure used to derive the observed RM images in order to ensure a proper comparison of the simulations with the data. By comparing our simulations with the observed polarization properties of the radio sources, we determined the strength and the power spectrum of the intra-cluster magnetic field fluctuations that reproduce the observation best.

By assuming that PKS 2149-158 and PKS 2148-158C lie at the same distance along the line-of-sight and by neglecting their three-dimensional structure, we conclude that the data are consistent with a power law magnetic field power spectrum with the Kolmogorov index $n = 11/3$ while the largest scales of the magnetic field fluctuations are of the order of 35 kpc. The average magnetic field strength at the cluster centre is about 3 $\mu$G and decreases in the external region as the square root of the electron gas density. The average magnetic field strength over the central 1 Mpc$^3$ is about 1 $\mu$G.

### Acknowledgements

We would like to express our gratitude to Gabriele Giovannini for the critical reading of the manuscript, and to Tiziana Venturi and Marco Bondi for many helpful discussions. D. G. wishes to thank the staff of the Astronomical Observatory of Cagliari for their hospitality and support during the development of this work. This research has been partially funded by the Grant ASI-INAF I/088/06/0 – High Energy Astrophysics. We made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.
