ABSTRACT
We have investigated the relationship between the kinematics and mass of young (<3 × 10^8 years) white dwarfs using proper motions. Our sample is taken from the colour selected catalogues of SDSS [Eisenstein et al. 2006] and the Palomar-Green Survey [Liebert, Bergeron & Holberg 2005], both of which have spectroscopic temperature and gravity determinations. We find that the dispersion decreases with increasing white dwarf mass. This can be explained as a result of less scattering by objects in the Galactic disk during the shorter lifetime of their more massive progenitors. A direct result of this is that white dwarfs with high mass have a reduced scale height, and hence their local density is enhanced over their less massive counterparts. In addition, we have investigated whether the kinematics of the highest mass white dwarfs (> 0.95 M☉) are consistent with the expected relative contributions of single star evolution and mergers. We find that the kinematics are consistent with the majority of high-mass white dwarfs being formed through single star evolution.

Key words: White Dwarfs – Galaxy: kinematics and dynamics – stars: kinematics

1 INTRODUCTION

Despite the significant work on both the kinematics and mass distribution of white dwarfs, very little work has addressed their connection.

The kinematics of galactic white dwarfs have been studied on numerous occasions with several motivations. They have proven useful in attempts to unravel the evolutionary history and progenitors of the various classes of white dwarfs [Sion et al. 1988; Anselowitz et al. 1999]. Interest in white dwarf kinematics was also prompted by the suggestion that halo white dwarfs could provide a significant contribution to Galactic dark matter [Oppenheimer et al. 2001; Reid 2005]. This effort has concentrated on the identification of halo white dwarfs and estimating the resultant density, which now appears to be a small contribution to the Galactic dark matter budget [Pauli et al. 2006]. Moreover, the mass distribution of the most common hydrogen rich (DA) white dwarfs has also been extensively investigated, particularly for white dwarfs with T ≥ 10,000 K which are hot enough for their masses to be deduced spectroscopically from fits to their Balmer lines [Liebert, Bergeron & Holberg 2003; Kepler et al. 2007; Vennes 1999]. The mass distribution shows a peak at 0.6 M☉ due to the relative abundance of their lower mass progenitors with a tail extending to higher masses formed from more massive progenitors.

The connection between the galactic kinematics of a group of thin disk objects and their progenitors is largely due to the process of kinematic disk ‘heating’ [Wielen 1977; Nordström et al. 2004]. The hot white dwarfs with short cooling ages we observe in the galactic neighbourhood today are formed from a wide range of progenitor masses (~ 0.8–8 M☉) and hence have a wide range in age. We therefore expect high-mass disk white dwarfs to have a low velocity dispersion in comparison to low-mass disk white dwarfs whose progenitors formed earlier. This connection was suggested in Guseinov, Novruzova & Rustamov (1983) who performed an analysis suggesting that white dwarfs with larger masses have smaller dispersions, however this was reinvestigated by Sion et al. (1988) with a larger sample of 78 DA white dwarfs where no evidence for any correlation was found. This paper redresses the connection between mass and kinematics with a greatly increased sample size.

The outline of the paper is as follows: In section 2 we discuss the sample selection and the calculation of distances and proper motions. In section 3 we discuss how we estimate the kinematics of the sample without radial velocity information. We use two methods, that of Dehnen & Binney (1998) (section 3.1), and a Markov Chain Monte Carlo (MCMC) where we marginalise over the unknown radial velocity (section 3.2). In section 4 we analyse whether the kinematics are consistent with single star evolution (SSE) both via analytic methods (section 4.1) and simulations (section 4.2). In section 5 we analyse whether the highest mass white dwarfs are largely formed through single star evolution or are the product of the merger of two lower mass white dwarfs. Finally, we discuss the implications of our findings on the scale height of white dwarfs in section 6.

For the reader in a hurry, the primary result of this paper, the relationship between the mass of young white dwarfs and their velocity dispersion, is shown in figure 3 and discussed in section 6. The implied scale heights, the second key result, are then discussed in section 6. These results have been checked using a Monte Carlo simulation of the formation and observation of an ensemble
of white dwarfs, which is described by flowcharts in figures 4, 5, 6, and 7. The process of choosing stars is described in figures 6, 7, and 8. The process of placing them in the disk is described, and in figure 8 the process of determining the observability of the simulated white dwarf is described.

2 SAMPLE

We investigate only hydrogen atmosphere (DA) white dwarfs due to the relative simplicity of their spectra and the resultant security of the spectroscopic masses. The sample of DA white dwarfs is taken from two sources, the Palomar-Green (PG) white dwarf survey (Liebert, Bergeron & Holberg 2005) and the SDSS DR4 white dwarf survey (Eisenstein et al. 2006). The SDSS sample is much larger than the PG sample. The PG sample is included as a demonstration that the results are secure, and not a result of systematics in SDSS, such as the complex selection of targets. For clarity we first discuss which types of white dwarfs we select, then discuss how the SDSS survey is dealt with, and finally how the PG survey was dealt with. The sample and its selection is summarised in table 1.

SELECTED WHITE DWARFS: Both PG and SDSS are colour selected, eliminating the kinematic biases inherent in proper motion based surveys, and contain spectroscopic determinations of surface gravity, log $g$, and effective temperature, $T_{\text{eff}}$, obtained by fitting the profile of the Balmer lines. We restrict the sample to objects whose fitted $T_{\text{eff}}$ was between 13,000 K and 40,000 K, since log $g$ appears to be systematically overestimated at low temperatures and $T_{\text{eff}}$ overestimated at higher temperatures (Eisenstein et al. 2006).

The fitted log $g$ and $T_{\text{eff}}$ are converted to masses and ages using the models of the carbon core white dwarf cooling models of Fontaine, Brassard & Bergeron (2001), with thick hydrogen layers of fractional mass $10^{-4}$ above 30,000 K. White dwarfs with inferred masses less than 0.47 $M_{\odot}$ are instead assumed to have helium cores, whose masses and ages are calculated from the models of Serenelli et al. (2001). Only objects with cooling ages below $3 \times 10^{8}$ years are included in the sample to avoid significant kinematic heating after white dwarf formation. The requirements of cooling age below $3 \times 10^{8}$ years and $T_{\text{eff}}$ above 13,000 K are competing. Above 0.60 $M_{\odot}$ the WDs cool more slowly and thus the age limit is used, while below 0.60 $M_{\odot}$ the temperature limit is used.

White dwarfs previously discussed in the literature as known members of binaries were removed from the samples.

SDSS SURVEY (EISENSTEIN ET AL. 2006): Many of the SDSS spectra have low signal-to-noise ratios and hence large errors on their fitted log $g$ and $T_{\text{eff}}$. To ensure accurate masses and photometric distances only objects whose spectra had a signal-to-noise ratio larger than 10 are included. The grid of model atmospheres fitted in the SDSS catalog extends only to log $g = 9$, and thus, for objects at this limit, the refitted log $g$ and $T_{\text{eff}}$ given in Kepler et al. (2007) were used.

Photometric distances to the white dwarfs in SDSS are calculated by minimising

$$\sum_{i=1}^{5} (m_i - [M_i(\log g, T_{\text{eff}})] + A_g, a_i + 5 \log d - 5)^2/\sigma_i^2$$

where $m_i$ and $\sigma_i$ are the 5 band SDSS photometry and their errors, $M_i$ are the model absolute magnitudes, $A_g, a_i$ is the reddening and $d$ the distance in parsecs. The photometric $\sigma_i$ is the quoted photometric error in SDSS each band added in quadrature to a systematic error of $(u, g, r, i, z) = (0.015, 0.007, 0.007, 0.007, 0.01)$ (Kleinman et al. 2004). Model absolute magnitudes are taken from the atmospheric models provided by Bergeron (1999). $A_g, a_i$ is the product of $R_V = 3.1$ extinction in each band of $(a_u, a_g, a_r, a_i, a_z) = (1.36, 1.00, 0.73, 0.55, 0.39)$ and the overall extinction $A_g$, which is constrained to lie between zero and the value of galactic extinction map of Schlegel, Finkbeiner & Davis (1998) at the position of the object considered.

The resulting distribution of $\chi^2$ values calculated by minimising equation 1 is plotted in figure 1. It closely resembles a $\chi^2$ distribution, but with an extended tail. Objects with reduced $\chi^2$ larger than 5 were removed from the sample, most of these objects show an excess towards the redder photometric bands, indicating they are in binaries with a cooler white dwarf companion. Errors in the photometric distance are taken to be the $\Delta \chi^2 = 1$ surface added in quadrature to the distance errors introduced through the uncertainty in log $g$ and $T_{\text{eff}}$.

Proper motions for the SDSS sample are taken from the catalogue of Munn et al. (2008). These proper motions are calculated from the USNO-B1.0 plate positions re-calibrated using nearby galaxies together with the SDSS position so that the proper motions are more accurate and absolute. By measuring the proper motions of quasars Munn et al. (2004) estimates that the 1σ error is 5.6 mas yr$^{-1}$.

PG SURVEY: For 132 stars in the PG survey, SDSS photometry was available and the same method was used as for SDSS stars. For the remaining objects the PG catalog photometric distances were used. These were estimated in Liebert, Bergeron & Holberg (2005) from comparison of the $V$ band magnitude with the predicted $M_V$ from the same models of Holberg & Bergeron (2006). Comparison of the stellar distances given by the two methods gives a standard deviation of 7 per cent. The majority of this error is ex-

---

\[ \sum_{i=1}^{5} (m_i - [M_i(\log g, T_{\text{eff}})] + A_g, a_i + 5 \log d - 5)^2/\sigma_i^2 \]

\[ \chi^2 = \sum_{i=1}^{5} (m_i - [M_i(\log g, T_{\text{eff}})] + A_g, a_i + 5 \log d - 5)^2/\sigma_i^2 \]

Figure 1, $\chi^2$ per degree of freedom (DOF) for the fitted photometric distance of the 1443 SDSS DA white dwarfs considered. A $\chi^2$ function with 3 DOF is plotted as the dotted line. Beyond $\chi^2 = 5$ the white dwarfs are rejected.
expected to be in the PG survey distances and hence a conservative 10 per cent error was applied to these.

Proper motions for PG white dwarfs that appear in SDSS are taken from the catalog of Munn et al. (2008). For the remaining objects, the PPMXL proper motion was used where available, which has typical 1σ error of ∼8 mas yr⁻¹ (Roeser, Demleitner & Schilbach 2010).

Finally 4 objects in the PG sample have no reliable PPMXL proper motion, primarily due to a spurious matching of objects between epochs. For these, the proper motion was calculated directly between the scanned POSS-I and POSS-II plates. The proper motion was measured relative to nearby faint stars of similar magnitude corrected for galactic rotation (see Section 3.1). Typical errors estimated from the proper motions of stars of similar magnitude to be 11 mas yr⁻¹. We emphasize that only 4 of 1491 white dwarfs use this method, and none have mass above 0.95 M☉ analyzed in more detail in Section 5.

Final Sample: The resulting sample of 1443 SDSS and 211 PG white dwarfs contains young DA white dwarfs with reliable masses, proper motions and photometric distances. The mass distribution of the samples is shown in figure 2. The process of constructing the sample together with numbers of objects is summarised in Table 1.

|                  | PG     | SDSS   |
|------------------|--------|--------|
| Number of DA White Dwarfs with good photometry not known to be binaries | 299    | 6926   |
| of these number with signal-to-noise > 10 | 299    | 3125   |
| of these number with 13,000 K < T_eff < 40,000 K | 215    | 1555   |
| of these number with age < 3 × 10⁶ yrs | 211    | 1491   |
| Distance source: |        |        |
| Liebert, Bergeron & Holberg (2005) | 79     | 0      |
| SDSS Photometry | 132    | 1491   |
| of these number rejected with χ² > 5 | 0      | 48     |
| Proper Motion Source: |        |        |
| Munn et al. (2008) | 153    | 1443   |

| Manual measurement from POSS I/II | 4      | 0      |
| Table 1. Summary of sample

3 KINEMATICS WITHOUT RADIAL VELOCITIES

We now turn to calculating the mean velocity and the velocity dispersion for our sample. While radial velocities are required to completely determine the kinematics of an individual object, bulk kinematic properties such as the mean velocity and the velocity dispersion can be determined from only transverse motions.

We use two methods to do so, the frequentist method used in section 3.1 and a Markov Chain Monte Carlo in section 3.2. Both methods give similar results which are summarised in Table 2.

3.1 Method of Dehnen and Binney (1998)

The method used here is adapted from Dehnen & Binney (1998). First the observed proper motions in galactic coordinates, µₜ and µₖ, are corrected for Galactic rotation through

\[
\begin{align*}
\mu_t &= \mu_t^{obs} - A \cos(2\ell) - B \\
\mu_b &= \mu_b^{obs} + A \sin(2\ell) \cos b \sin b.
\end{align*}
\]

using A = 14.82 km s⁻¹ kpc⁻¹ and B = −12.37 km s⁻¹ kpc⁻¹ (Feast & Whitelock 1997). In galactic coordinates where the components are directed towards the galactic centre, in the direction of galactic rotation, and towards the north Galactic pole we observe the velocity

\[
V_\perp = 4.74d \left(\begin{array}{c}
-\mu_t \sin \ell \cos b - \mu_b \cos \ell \sin b \\
\mu_t \cos \ell \cos b - \mu_b \sin \ell \sin b \\
\mu_b \cos b
\end{array}\right) \text{km s}^{-1}
\]

with d in kpc and proper motions in mas yr⁻¹. This is the projection of the velocity V onto the sky plane though the projection matrix

\[
V_\perp = A \cdot V, \quad A = I - \hat{r} \otimes \hat{r}
\]

where \(\hat{r}\) is the unit vector to the star.

Next the quantity \(S^2\) is formed through

\[
S^2(V_0) \equiv \langle |V_\perp - A \cdot V_0|^2 \rangle.
\]

Under the assumption that the positions of the observed objects are uncorrelated with the velocity, then the choice of \(V_0\) that minimises \(S^2\) is the mean velocity. Also \(S^2\) at the minimum is a measure of the dispersion of the group.

Dehnen & Binney (1998) then calculate all independent six elements of the dispersion tensor. Unfortunately, this entails estimating nine parameters which limits its use to samples with large numbers of objects. This would require excessively wide bins for the high-mass region where there are few objects. Instead we choose to make further assumptions about the objects’ velocities in order to reduce the number of fitted parameters. The mean velocity of each group towards the galactic centre and the north Galactic pole is simply a result of the solar motion and we take these to be 10.00 km s⁻¹ and 7.17 km s⁻¹ respectively (Dehnen & Binney 1998). The mean velocity in the direction of galactic rotation, \(V_0\), is kept as a free parameter since in addition to the solar motion this varies between groups due to asymmetric drift. We also assume that the dispersion tensor takes the form

\[
\sigma = \sigma_1 \text{diag}(1, 1, 1, 1, 1, 1)
\]

which is accurate for main sequence stars in the solar neighbour-
hood (Dehnen & Binney, 1998). This reduces the number of parameters for each group to the asymmetric drift $V_0$ and the normalisation of the dispersion tensor $\sigma_1$.

$V_0$ is calculated by minimising equation [5] and then $\sigma_1$ is estimated though a Monte-Carlo simulation: Since $S^2$ is a measure of the dispersion, an initial estimate of $\sigma_1^2$ is taken to be $S^2$, and a set of simulations is performed where a new velocity is chosen for each white dwarf at its position in the sky from the isothermal distribution with the assumed dispersion tensor and the calculated mean velocity. The error in tangential velocity, assumed to be Gaussian, is added to this. The set of simulations produces a distribution for each white dwarf at its position in the sky from the isothermal distribution function, and normally distributed error in proper motion. The unknown radial velocity is integrated over analytically. Exceptions include the reduced degrees of freedom. In particular, the results, aside from the larger errors, particularly in the underpopulated bins due to the reduced degrees of freedom. In particular, the results are insensitive to allowing vertex deviation.

Again, the dispersion tensor and mean were constrained to reduce the number of parameters. We use flat priors on the dispersion and asymmetric drift. The expression for the likelihood was used to calculate the maximum likelihood estimate of the dispersion tensor, while errors were estimated from a MCMC using Metropolis-Hastings sampling. When the constraints on the dispersion tensor and mean velocity were relaxed this did not substantially alter the results, aside from the larger errors, particularly in the underpopulated bins due to the reduced degrees of freedom. In particular, the results are insensitive to allowing vertex deviation.

The fitting results for the SDSS and PG samples are summarised in table [2] and plotted in figure [3]. In addition, in figure [4] the raw transverse velocities measured from the proper motions for three groups of white dwarfs are shown. The lowest mass white dwarfs, $M < 0.45 M_\odot$, are expected to be predominantly formed through binary evolution and have a binary white dwarf partner. This potentially introduces errors into their photometric distances and so we do not consider them beyond simply stating the fitting results in table [2].

### 3.2 MCMC Estimate

In addition, a Markov Chain Monte Carlo (MCMC) likelihood based estimate of the kinematic parameters was obtained. We use uninformative flat priors for the fitted parameters.

We denote the probability that the velocity of the $i$th object was $V$ to be $P(V|D_i, \sigma)$ where $D_i = (l, b, d, \mu, \mu_b)$ is the data for the $i$th object together with the corresponding errors $\sigma$, $\mu$, and $\mu_b$ are the values corrected for galactic rotation by equation (2).

Under the assumption that positions are uncorrelated with velocity then the distribution function is a function only of velocity: $f(V)$. In addition, in what follows we do not consider the positions, but instead focus on the kinematics through the velocity $V$. Under these assumptions the overall likelihood for a set of observations of a group of white dwarfs is

$$\mathcal{L} = \prod_i \int dV f(V) P(V|D_i, \sigma)$$

$$\Rightarrow \log \mathcal{L} = \sum_i \log \int dV f(V) P(V|D_i, \sigma)$$

$$\equiv \sum_i \log \mathcal{L}_i.$$  

In calculating the likelihoods, $\mathcal{L}_i$, we assume a Schwarzschild distribution function, and normally distributed error in proper motion. The unknown radial velocity is integrated over analytically. Explicit expressions for $\mathcal{L}_i$ are given in appendix [A].

The fitting results for the SDSS and PG surveys. Low mass white dwarfs ($0.5 M_\odot < M < 0.75 M_\odot$) as solid black, high mass white dwarfs ($M > 0.95 M_\odot$) as dashed red, and intermediate mass white dwarfs ($0.75 M_\odot < M < 0.95 M_\odot$) as dotted green.
Table 2. Kinematic fitting results from the PG and SDSS samples described in section 3 using the methods of sections 3.1 and 3.2. \( M_{\text{low}} \) and \( M_{\text{high}} \) are in units of \( M_\odot \), while \( \sigma_1 \) and \( V \) are in \( \text{km s}^{-1} \). \( N \) is the number of white dwarfs in each mass bin.

| \( M_{\text{low}} \) | \( M_{\text{high}} \) | \( N \) | PG | SDSS |
|-----------------|-----------------|-----|-----|------|
|                 |                 |     | Dehnen & Binney (1998) | Dehnen & Binney (1998) |
|                 |                 |     | \( \sigma_1 \) | \( \sigma_2 \) | \( \sigma_1 \) | \( \sigma_2 \) |

4 EXPECTATIONS FROM SINGLE STAR EVOLUTION

4.1 Analytic

In this section we describe the reasons for the relationship WD mass and dispersion within a simple analytic model, before moving onto the more complex Monte Carlo simulations of section 4.2.

Within the framework of single star evolution (SSE) an ensemble of white dwarfs with the same mass would be expected to have a dispersion \( \sigma(t_{\text{TOT}}) \), where \( \sigma(t) \) is the disk heating relation, and \( t_{\text{TOT}} \) is the total age of the white dwarf including its precursor lifetime (i.e. total pre-white dwarf stellar lifetime). Here \( t_{\text{TOT}} \) will be given by \( t_{\text{TOT}} = t_{\text{WD}} + t_{\text{SSE}}(M_i(M_{\text{WD}})) \) where \( t_{\text{WD}} \) is the cooling age of the white dwarf and \( t_{\text{SSE}}(M_i(M_{\text{WD}})) \) is the total precursor lifetime, which is a function of the white dwarf mass through the initial-final mass relation (IFMR) \( M_i(M_f) \). Two components of this prediction are particularly uncertain: the disk heating relation and the IFMR. We discuss these now.

The best constraints on the IFMR come from open clusters. Spectroscopic fits of the masses of white dwarfs give the final mass. The initial mass is estimated using isochrone fitting to the main sequence turnoff to calculate the age of the cluster, which finally allows the corresponding initial mass to be inferred using the precursor lifetime (Catalán et al. 2008). This method has succeeded in producing IFMRs with a typical uncertainty of less than 20%. The strong dependance of the precursor lifetime on mass however makes this a considerable uncertainty in the dispersion relation.

The most accurate data on the disk heating relation is given in Nordström et al. (2004) from an analysis of F and G dwarfs with radial velocities and Hipparcos data, although this data still permits a range of heating models (Seabroke & Gilmore 2007). However, for consistency, we instead use the disk heating models estimated in Just & Jahreiß (2010), since we also use their companion star formation histories.

The effect of these model uncertainties are shown in figure 5 for the models described in table 3. Qualitatively the results appear to agree with the predicted relations: for white dwarfs more massive than 0.75 \( M_\odot \) the white dwarf progenitors precursor lifetime is short and there is little dependance of the kinematics on mass. Below 0.75 \( M_\odot \) the dispersion sharply increases as the progenitor lifetime approached 1 Gyr and longer where the disk heating is significant.

However, while qualitatively the results in figure 5 are consistent, there is quantitative disagreement. To assess this disagreement we turn to a more sophisticated Monte Carlo treatment.

4.2 Monte Carlo

As a quantitative check of our results in section 4.1 we have performed a Monte Carlo simulation of the production, kinematics, and observation of the white dwarfs in the solar neighbourhood, as described in this section. We also describe the simulated selection and observation of these white dwarfs by SDSS and PG. We perform this simulation to assuage fears that our results could be impacted by effects such as selection biases.

This process is somewhat involved, and so for clarity it is summarised in the flow charts in figures 6-8. The final results of the Monte Carlo simulation are compared with the white dwarf sample in figure 10.

PICKING STARS: The initial mass was drawn from a Kroupa IMF and one of two star formation histories (Table 3). If this resulted in a white dwarf at the present time with an age less than \( 3 \times 10^8 \) years, and a temperature between 13,000K and 40,000K using the cooling models of Wood (1995) as explained in section 2, then it was included in the simulation. See figure 6 for synopsis.

PLACING STARS IN DISK: If a star has been included in the simulation, it is given a velocity dispersion taken from the previously described disk heating models of table 3 and axis ratios of the...
velocity ellipsoid of 1:1/1.4:1/2.2 (Dehnen & Binney 1998). Its velocity in the disk was drawn from a Gaussian with these widths and it was placed in the plane of the Galaxy using a radial exponential disk with a scale length of 2.5 kpc. Since the furthest > 0.47 M⊙ WD projected into plane is less than 1 kpc, only WDs placed within this distance are simulated further.

For an isothermal population the vertical position, \( z \), and velocity, \( v_z \), are given by

\[
\begin{align*}
  f_z(E_z) &\propto \exp\left(-\frac{E_z}{\sigma_z^2}\right) \\
  \Phi_z(z) &\propto \exp\left(-\frac{z^2}{2\sigma_z^2}\right) \exp\left(-\frac{\Phi_z(z)}{\sigma_z^2}\right),
\end{align*}
\]

where \( \Phi_z \) is the gravitational potential. Each star’s velocity is thus drawn from a Gaussian with standard deviation given by the previously calculated \( \sigma_z \), while \( z \) is chosen by first drawing \( \Phi_z(z) \) from an exponential distribution with scale \( \sigma_z^2 \), and then inverting this to calculate \( z \). We use the mass models of Holberg & Flynn (2000) for \( \Phi_z(z) \).

This process of placing white dwarfs in the local galactic disk is summarised in figure 6.

**Figure 6.** Flowchart illustrating the process of simulating white dwarfs formed from single star evolution (SSE). If a star reaches the final stage, then it is placed in the disk using a process described by the flowchart shown in figure 6.

For white dwarfs in the PG survey the apparent \( U \) and \( B \) magnitude is calculated from the models of Holberg & Bergeron (2000) with a 0.27 mag error added to each to mimic the photometric errors in PG (Liebert, Bergeron & Holberg 2005). If it is bluer than \( U - B = -0.46 \) and brighter than the \( B \) band magnitude limit for the PG plate on which it lies then it is considered observed.

For SDSS the spectroscopic targeting is more complex (Kleinman et al. 2004), and the strategy was to construct an empirical observational probability for a star at each magnitude and colour. A four dimensional table of probability of spectroscopic follow up was constructed in \((r, u - g, g - r, r - i)\) grouped in 0.2 mag bins from the SDSS DR4 clean photometry. The expected spectroscopic signal-to-noise was calculated using a quadratic least squares fit to the observed signal-to-noise ratio as a function of \( g \)-band magnitude together with normally distributed scatter in signal-to-noise with standard deviation of 1.7. If the signal-to-noise ratio was greater than 10 it was included in the mock sample.

Finally, measurement errors in mass of 0.03 M⊙ and proper motion errors of 5.6 mas yr\(^{-1}\) are introduced.

The process of assessing if each white dwarf is observed by the PG or SDSS surveys is summarised in figure 8. In all simulations we simulate a total of \( \sim 2 \times 10^{11} \) objects.

**MONTE CARLO RESULTS:** The results of this simulation are shown in figure 10. As a further check that the simulated white dwarfs have the correct kinematics we plot the distributions in the \( U, V \) and \( W \) directions (directed towards the galactic centre, in the direction of galactic rotation, and towards the north Galactic pole respectively) in figure 9.

The results of the single star evolution (SSE) simulation, described in this section, closely agree with the observations, modulo the normalisation factor. We do not concern ourselves with this overall normalisation, however the normalisation factor is typically

---

**Table 3.** Model input parameters for the models of single star evolution (SSE).

| Model | \( \sigma(t) / \text{km s}^{-1} \) | \( M_i(M_{\text{WD}}) / M_\odot \) | \( t_{\text{SSE}}(M_i) / \text{Gyr} \) | \( \text{SFR}(t)^a \) |
|-------|-------------------|-----------------|-----------------|-----------------|

Figure 8. Flowchart illustrating the process of simulating whether white dwarfs are observed. This process is undertaken if a star has reached the final stage of the flowchart shown in figure 7.

$\lesssim 2$. The simulation also does not produce white dwarfs below $\approx 0.47$ $M_\odot$, which are generally expected to form through binary evolution. As may be expected from the analytic models plotted in figure 5 the models in table 3 all produce white dwarfs that reasonably closely explain the observed samples and their kinematics and so we only plot the results of only one representative model in figure 10.

## 5 EXPECTATIONS FROM BINARY STAR EVOLUTION

It has been suggested that the majority of high-mass white dwarfs were formed from mergers of binary white dwarfs, both on the basis of their number density [Liebert, Bergeron & Holberg 2005] and a possible peak at $1 M_\odot$ [Vennes 1999]. To test this hypothesis we use two binary evolution codes (discussed in section 5.1) to perform binary population synthesis (described in section 5.2), and ultimately what fraction of the sample is likely to have had a binary WD progenitor (section 5.3).

5.1 Binary Evolution Codes

To address the considerable uncertainties in binary evolution, two binary evolution codes were used. Specifically, the BSE code described in Hurley, Pols & Tout (2000), and the SeBa code described in Nelemans et al. (2001). Both codes use the same approach to modelling binary evolution: semi-analytic fits to the structure and evolution of isolated stars are combined with prescriptions for interactions between the stars.

There are four key initial conditions that govern the evolution of a binary: the initial primary mass $M_{1i}$, the initial secondary mass $M_{2i}$ (or equivalently the mass ratio $q_i = M_{1i}/M_{2i}$), the initial binary semi-major axis $a_i$, and the initial eccentricity $e_i$.

One slice through the four-dimensional space of initial conditions $(M_{1i}, q_i, a_i, e_i)$ showing those conditions which result in the merger of a pair of white dwarfs is shown in figure 11.

The differences between the BSE code and SeBa code in figure 11 are striking, and are largely due to the different binary evolution prescriptions, and in particular the treatment of the Roche lobe overflow (RLOF) and common envelope (CE) phases.

For the specifics of the treatment of the RLOF phase and its treatment in the BSE and SeBa codes we refer the reader...
Figure 10. Comparison between the observed white dwarfs as the solid lines, and the Monte Carlo simulations of single star evolution described in section 2. Specifically low-mass white dwarfs \((0.5 \, M_\odot \leq M_1 + M_2 < 0.75 \, M_\odot)\) are plotted in black, high-mass \((M_1 + M_2 > 0.95 \, M_\odot)\) white dwarfs in red, and intermediate mass white dwarfs \((0.75 \, M_\odot \leq M_1 + M_2 < 0.95 \, M_\odot)\) in green. The simulation plotted is model D from table 3.

| Model | Evolution Code | CE Prescription | \(\alpha_{CE}\) | \(\gamma\) |
|-------|----------------|-----------------|---------------|-----------|
| i     | BSE            | \(\alpha\)      | 2             | -         |
| ii    | BSE            | \(\alpha\)      | 1             | -         |
| iii   | SeBa           | \(\gamma\alpha\)| 2             | 1.5       |
| iv    | SeBa           | \(\alpha\)      | 2             | -         |

Table 4. Summary of the four binary evolution models considered. The BSE code is that described by Hurley, Pols & Tout (2000), and the SeBa code is described in Nelemans et al. (2001). The common envelope (CE) prescription describes how the two phases of common envelope evolution are treated. For example \(\gamma\alpha\) describes treatment of the first phase through the \(\gamma\) parameterisation and the second through the \(\alpha\) parameterisation. We refer the reader to Nelemans et al. (2001) for the definition and descriptions of these parameterisations.

5.2 Binary Population Synthesis

We now describe our method of binary population synthesis.

We use the same distributions in the parameters \((M_1, q, a_i, e_i)\) as Hurley, Pols & Tout (2000) with the exception of the IMF for which we use a Kroupa (2001) IMF as opposed to a Miller & Scalo (1979) IMF. For the reference probability distributions:

\[
P(M_1) \propto M_1^{-1.35} \quad 0.8 < M_1 \leq 10, \\
P(q) \propto \text{const.} \quad 0 < q \leq 1, \\
P(\log a_i) \propto \text{const.} \quad 0 < \log a_i / R_\odot \leq 5, \\
P(e_i) \propto e_i \quad 0 \leq e_i < 1.
\]

Our approach to simulating the results of binary star evolution is to first produce a 4-dimensional grid of binary simulations in the parameters \((M_1, q, a_i, e_i)\). Grid points were linearly spaced in \(M_1\) between 0.8 and 10 \(M_\odot\), linearly spaced in \(q\) between 0 and 1, logarithmically spaced in \(a_i\) between 1 and \(10^3\) \(R_\odot\), and linearly spaced in \(e_i^2\) between 0 and 1. The grid size used was a \(25 \times 25 \times 50 \times 10\) grid \((M_1, q, a_i, e_i)\), respectively. With this choice of grid combined with the distributions in equation (11) the population synthesis is particularly simple: an initial primary mass is drawn from the Kroupa (2001) IMF and a random binary from the closest corresponding \((q, a_i, e_i)\) slice is chosen. In all simulations a total of \(\sim 10^{13}\) objects are places in the disk.

The process of simulating stars formed from binary evolution is summarised in figure 12.

In what follows we concern ourselves with the merger of CO+CO white dwarfs, since these are the mergers proposed to result in \(\sim 1 \, M_\odot\) white dwarfs. Thus, in figure 13 we plot the rate at which pairs of white dwarfs with sub-Chandrasekhar total mass merge as calculated from our binary population synthesis of...
Get random distance from galactic center, \( R \), from number density \( d\nu \propto \exp(-R/R_0)RdR \)

Get random orientation in galactic plane from \( \text{sun } \phi \) from uniform distribution

Is WD within 1 kpc of the sun in the galactic plane?

No

Yes

Get WD from SSE/BSE with mass \( M_{\text{WD}} \) and age since star formation \( t_{\text{TOT}} \)

Get \( \sigma_z \) from age-dispersion relation using \( t_{\text{TOT}} \)

Get random \( v_z \) and \( \Phi_z(z) \) assuming isothermal distribution \( f_z \propto \exp(-v_z^2/2\sigma_z^2)\exp(-\Phi_z(z)/\sigma_z^2) \)

Calculate \( z \) by inverting the \( \Phi_z(z) \) given by the mass model of Holmberg & Flynn (2000)

Get random \( v_x \) and \( v_y \) assuming Schwarzschild distribution with \( \sigma \) from age-dispersion relation

Add solar motion and asymmetric drift of \( (v_y) = -\sigma_y^2/80 \text{ km s}^{-1} \) (Dehnen and Binney, 1998)

Is the white dwarf observable at this position? See observability flow chart

Figure 7. Flowchart illustrating the process of placing white dwarfs in the galactic disk and picking their velocity. This process is undertaken if a star reaches the final stage of the flowchart shown in figure 4. If a star reaches the final stage of this flowchart, the observability is finally determined using the algorithm described in the flowchart shown in figure 8.

Figure 9. Histograms showing the agreement between the observed and simulated velocity distribution in \( U, V, W \) directions of SDSS WDs. The black line is the observed distribution, while the dashed red line is the distribution of the SSE simulation for model C. Zero radial velocity is artificially assumed, and number of simulated WDs is normalised to the number observed. \( U \) is directed towards the galactic centre, \( V \) in the direction of galactic rotation, and \( W \) towards the north Galactic pole.

Figure 11. Comparison of the WD+WD merger outcomes from the SeBa and BSE codes with their default prescriptions for binary evolution. All simulations use an initial mass ratio of \( q_i = 0.5 \) and eccentricity of \( e_i = 0 \). Green corresponds to CO+CO, red He+CO and blue He+He. The lighter green are sub-Chandrasekhar (\( M_1 + M_2 < 1.4 \, M_\odot \)) mergers, and the dark green super-Chandrasekhar.
5.3 Proportion of high-mass White Dwarfs Formed in Mergers

To assess the possible proportion of high-mass white dwarfs that formed through mergers, the CO+CO merger products with $0.95 \, M_\odot \leq M_1 + M_2 < 1.4 \, M_\odot$ from the binary population synthesis, are subjected to the same process as the single population synthesis results i.e. they are placed locally in the disk according to the method summarised in figure 7 and their observability in the SDSS and PG samples assessed according to figure 8.

We assume that no mass is ejected during the merger so that resultant white dwarf has mass $M_{WD} = M_1 + M_2$. We also assume that the merger reheats the white dwarf sufficiently that the white dwarf has a cooling age of $$t_{WD} = t_{form} - t_{merge}$$

where $t_{form}$ is the time prior to the present at which the binary initially formed, and $t_{merge}$ is the length of time it took for the merger to occur, including the precursor lifetime. The resulting cumulative transverse velocity of $0.95 \, M_\odot \leq M_1 + M_2 < 1.4 \, M_\odot$ CO+CO merger products are shown in figure 14.

In figure 14 and the following we have combined the PG and SDSS samples to improve the statistics. We combine the Monte Carlo results by the empirical proportions of WDs in this sample i.e. the observed PG to SDSS ratio of 5:9. Note however there is a possible discrepancy between the two samples in this high mass bin. In particular the SDSS sample has few low velocity (< 14 km s$^{-1}$) white dwarfs (see the bottom right panel of figure 14), and this results in a 12% probability that they are drawn from the same distribution.

The distribution of transverse velocities in figure 14 shows that despite the uncertainties in binary evolution resulting in very different binary histories (figure 11) and overall merger rates (figure 13), the resultant velocity distributions are very similar. This is a result of the $\sim t^{-1}$ merger time distribution at late times discussed previously.

The results in figure 14 naturally lead the question of what fraction of mergers is consistent with the data to be addressed. We wish to assess the fraction of high-mass galactic white dwarfs formed by binary mergers (BSE) which we parameterise by $\theta$. This results in a fraction $1 - \theta$ from single star evolution (SSE). To assess a value of $\theta$ for a given SSE and BSE Monte Carlo realisation we first calculate the galactic formation rate of high-mass WDs from SSE and BSE in this realisation, which we denote $\Gamma_{SSE}$ and $\Gamma_{BSE}$ respectively. Then, for both PG and SDSS we make $\alpha$ copies of the BSE objects simulated as observed, and $\beta$ copies of objects simulated as observed from SSE. Assuming that equal numbers of objects were simulated in both the SSE and BSE realisations, then the two simulated samples combined have a galactic BSE fraction of

$$\theta = \frac{\beta \Gamma_{BSE}}{\beta \Gamma_{BSE} + \alpha \Gamma_{SSE}}$$

To test whether the data is consistent with this realisation, we use the two sample Anderson-Darling statistic [Pen1974]. The Anderson-Darling test considers the difference between the samples across the entire distribution, and so is more statistically powerful that the more commonly used Kolmogorov-Smirnov test which depends only on the extremum. The number of simulated white dwarfs is always much larger, by at least a factor of ten, than the number observed.

The results for one particular choice of SSE and BSE model are shown in figure 15(a). In figure 15(b) we show the combined

---

**Figure 12.** Flowchart illustrating the process of simulating white dwarfs formed from binary star evolution.

**Figure 13.** Merger rates of CO+CO WDs with sub-Chandrasekhar total mass following a burst of star formation. The error bars are purely statistical due to the finite size of the simulated binary grid. Lines are models i-iv as solid line, dotted line, dashed line, and dash-dot line respectively. The models are described in table 8. SNuM = $1/(100 \, \text{yr})/(10^{10} \, M_\odot)$.
and PG resulting from the merger of CO+CO WDs with 0.95 < $M_\text{Z}/M_\odot$ < 1.4. Lines are the BSE code with $\alpha_{\text{CE}}\lambda = 2$ (solid blue line, model i), the BSE code with $\alpha_{\text{CE}}\lambda = 1$ (dotted blue line, model ii) the SeBa code using the $\gamma\alpha$ common envelope prescription (dashed blue line, model iii) and the SeBa code using the $\alpha\alpha$ prescription (dash-dot blue line, model iv). Both SeBa models use $\alpha_{\text{CE}}\lambda = 2$ and $\gamma = 1.5$. The red line is the predicted distribution of transverse velocities resulting from single star evolution to a 0.95 < $M_\text{Z}/M_\odot$ < 1.4 white dwarf according to model A in table 5 and the black line are the observed distributions. All BSE models use a constant SFR and the disk heating relation of model A in table 3.

This is a result of the lack of low velocity (< 14 km s$^{-1}$) white dwarfs in the SDSS sample. It may be that the lack of low velocity white dwarfs in SDSS is a statistical anomaly, since the number of objects is small. In theory this would be taken account of in the analysis described above, however young stellar objects can display prominent substructure in their kinematics as a result of moving groups (e.g. Dehnen 1998). This would have the result of both reducing the effective sample size, and producing a very different velocity distribution than the Schwarzschild distribution assumed in the SSE Monte Carlo. There are indications that this is the case, since when the SDSS objects are plotted in the $U - V$ plane (assuming zero radial velocity) 7 of the 9 objects lie in the negative U, negative V quadrant. Depending on the unobserved radial velocity, many of these could have kinematics consistent with the Pleiades and Hyades moving groups. Indeed it has been shown that the the white dwarf GD 50, has a velocity and cooling age consistent with a Pleiades origin (Dobbie et al 2006).

That the data rules out a white dwarf merger origin for the majority of high-mass white dwarfs appears more secure, despite the apparent consistency of the SDSS sample with the BSE simulations: The PG sample is entirely consistent with SSE, and neither sample contains a high-mass white dwarf travelling at > 50 km s$^{-1}$ which would be convincing evidence of a BSE origin for some high mass white dwarfs. This is not surprising, since the expected number of merger products observed in PG and SDSS ($N_{\text{BSE}}$ in table 5) is significantly smaller than the observed number of objects.

We note that a simpler empirical test for the origin of the high-mass white dwarfs is suggested by figure 4. The distribution of high-mass white dwarfs is consistent with the velocity distribution of the intermediate group that displays the kinematics of young objects at the 13 per cent level by the Anderson-Darling test. This ignores the selection effects which the Monte Carlo simulation addresses, but does suggest that the entire combined group of high mass white dwarfs is broadly consistent with SSE.

### 6 SCALE HEIGHTS

One of the key results of this study is that hot white dwarfs of mass $\gtrsim 0.75M_\odot$ had much shorter main sequence lifetimes than their lower mass counterparts, and hence their kinematics are characteristic of young stars. A direct result of this is that these higher mass white dwarfs will have reduced scale height. This is vitally important to consider when calculating the formation rate as a function of mass using local samples such as in Liebert, Bergeron & Holberg (2005) or Kepler et al. (2007) or producing galactic white dwarf simulations such as Nelemans et al. (2001).

Unfortunately, neither the SDSS or PG sample allow accurate direct determination of the scale height of each white dwarf population, particularly the rare and less luminous high-mass groups. Instead, here we list the expected scale height by comparison with the BSE models that appear to accurately describe the kinematics. We do this to allow simple initial corrections without resorting to the simulations of the type performed in this work. The scale height, $h$, was defined through

$$\nu(z) = \nu_0 \text{sech}^2 \left( \frac{z}{2h} \right),$$

where $\nu(z)$ is the stellar number density in terms of the height above the plane of the galactic disk, $z$. The scale height, $h$, was estimated by constraining equation (12) to give both the correct overall number and central WD density, $\nu_0$. We choose this method since the most common usage of the scale height is to calculate galactic birthrates from local densities. The results are give in table 6. Note that the higher mass groups smaller scale height results in a local density enhanced by more than a factor of two over the more common low-mass group. In particular, the apparent excess of high-mass white dwarfs found in the PG survey (discussed in section 6 of Liebert, Bergeron & Holberg 2003) can be naturally explained by their lower scale height, which causes a high abundance in this relatively local survey. That the number of high-mass white dwarfs
is consistent with single star expectations in PG is confirmed by the number of expected white dwarfs from single star evolution in table 5.

7 SUMMARY

We have analysed the kinematics of young (< 3 x 10^8 years) DA white dwarfs from both the PG and SDSS surveys and find a strong connection between their mass and kinematics: low-mass

| SFR | SSE Model | BSE Model | θ_fid | PG N_{SSE} N_{BSE} | SDSS N_{SSE} N_{BSE} | P(θ_fid) | θ(P > 0.01) |

Figure 15. Plots showing the calculation of the galactic formation fraction of high-mass white dwarfs formed in mergers during binary star evolution in model C compared to single star evolution model iii.

Table 5. Summary of the results of calculation of the fraction of high-mass white dwarfs formed in mergers compares to single star evolution. The SSE models are described in table 3, and the BSE models are described in table 4. Γ_{BSE} is the galactic formation rate (in yr^{-1}) from binary star evolution assuming that the merger of two CO white dwarfs with combined mass between 0.95M_⊙ and 1.4M_⊙ results in a high-mass white dwarf. Γ_{SSE} is the galactic formation rate from single star evolution. θ is the galactic fraction of high-mass white dwarfs formed from BSE so that the fiducial value is given by θ_fid = Γ_{SSE} / Γ_{BSE}. The numbers N_{SSE} and N_{BSE} are the predicted observed numbers from SSE and BSE evolution respectively in the PG and SDSS samples. P(θ_fid) is the probability that both the PG and SDSS velocity distributions are consistent with θ_fid using the Anderson-Darling statistic. θ(P > 0.05) is the range of θ values which have a probability of being consistent with the data greater than 1 per cent. The fiducial value of θ is calculated assuming a 50 per cent binary fraction (i.e., two-thirds of all stars formed in binaries). Both SSE and BSE models use the same disk heating model and star formation history: model C of table 3 for the constant SFR models, and model D for the exponential.
white dwarfs (0.45 M\(_\odot\) \(\leq M_1 + M_2 < 0.75\) M\(_\odot\)) display the kinematics of old stars, with higher velocity dispersion (\(~ 46\) km s\(^{-1}\)) and asymmetric drift, while higher mass white dwarfs (0.75 M\(_\odot\) \(\leq M_1 + M_2 < 0.95\) M\(_\odot\)) display the kinematics of young stars with a velocity dispersion of only \(~ 19\) km s\(^{-1}\). We have shown in section 3 that this is expected due to the shorter precursor lifetime of the more massive progenitors, and that there is agreement both on simple analytic grounds (section 4.1) and more quantitative Monte Carlo simulations of the PG and SDSS samples (section 4.2).

A further key conclusion is that the white dwarf scale height and its variation with age and mass is vitally important to consider when calculating birth rates based on local samples (section 4.3).

In addition, we have separately analysed the highest mass white dwarfs (\(M > 0.95\) M\(_\odot\), section 5), since it has been suggested that many of these formed as a result of the merger of two lower mass CO white dwarfs. We find at present a discrepancy in the SDSS velocity distribution where no high-mass white dwarfs with transverse velocity less than 14 km s\(^{-1}\) is detected. This results in a velocity distribution that within our statistical framework is inconsistent with purely single star evolution. We argue this is likely to an anomaly, either be a statistical, or a result of a number of these white dwarfs being members of moving groups. We find that, even under the most optimistic binary evolution models, we would only expect to find 3 white dwarfs formed via white dwarf binary mergers and that the apparent excess of high mass white dwarfs found in PG is caused by their reduced scale height. In addition, we note the kinematic ‘smoking gun’ of some fraction of high-mass white dwarfs coming from binary evolution would be high-mass white dwarfs traveling at \(> 50\) km s\(^{-1}\), of which none are found in PG or SDSS.

APPENDIX A: LIKELIHOODS

Here we give our expressions for the proper motion likelihoods of an individual object. These largely follow Ratnatunga, Bahcall & Casertano (1989), modified to include errors in proper motion. We ignore errors in sky position \((\ell, b)\), which are small.

Assuming a Schwarzschild distribution function, then, in coordinates aligned with the principle axes of the velocity ellipsoid,

\[
f(V) = \frac{1}{\sqrt{8\pi\sigma_1\sigma_2\sigma_3}} \exp\left(-\left(V - V_0\right)^T \cdot \Gamma \cdot (V - V_0)\right),
\]

where \(\Gamma = \text{diag}(1/2\sigma_1, 1/2\sigma_2, 1/2\sigma_3)\) and \(V_0\) is the mean velocity. Ignoring errors in distance, we then rotate to axes aligned with the sky plane, and integrate over the unobserved radial velocity, which, in this case, is a nuisance parameter.

We define, \(\Lambda\), to be the dispersion tensor rotated into the coordinate system, \((\ell, b, d)\), aligned with the sky plane. This will be given by \(\Lambda = R \cdot \Gamma\), where \(R\) is a rotation matrix (given explicitly as equation A4 in Ratnatunga, Bahcall & Casertano 1989).

The probability distribution, after integrating over the radial velocity as a nuisance parameter, is an ellipsoid in the sky plane

\[
p(v_\ell, v_b) = C' \exp\left[-\alpha(v_\ell - \bar{v}_\ell)^2 - \beta(v_b - \bar{v}_b)^2 - 2\gamma(v_\ell - \bar{v}_\ell)(v_b - \bar{v}_b)\right],
\]

where \(\bar{v}_\ell\) and \(\bar{v}_b\) are the components of \(V_0\) in the directions of \(l\) and \(b\) (which can be obtained via \((\bar{v}_\ell, \bar{v}_b, \bar{v}_d) = R \cdot V_0\)) and \(\alpha, \beta, \gamma, \) and \(C'\) are given by

\[
\alpha = \Lambda_{22} - \Lambda_{12}^2/\Lambda_{11},
\]

\[
\beta = \Lambda_{33} - \Lambda_{13}^2/\Lambda_{11},
\]

\[
\gamma = \Lambda_{23} - \Lambda_{12}\Lambda_{13}/\Lambda_{11},
\]

\[
C' = \sqrt{\alpha - \gamma^2}/\pi.
\]

For each object we have measurements of \(v_\ell\) and \(v_b\), together with an associated velocity error \(\sigma\). Integrating over the ‘true’ \(v_\ell\) and \(v_b\) gives the log likelihood used in equation 9 as

\[
\log \mathcal{L}_i(v_\ell^{\text{obs}}, v_b^{\text{obs}}) \equiv \log \int dV \mathcal{f}(V) P(V | v_\ell^{\text{obs}}, v_b^{\text{obs}}, \sigma)
\]

\[
= \log C'' - \frac{\delta}{2} \frac{\alpha + \delta}{\sqrt{\alpha + \delta} - \gamma^2} \left[\left(\Delta v_\ell^2 + \Delta v_b^2\right)\left(\alpha - \gamma^2\right) + \delta(\Delta v_\ell^2 + \alpha \Delta v_b^2 + 2\gamma\Delta v_\ell\Delta v_b\right)\right],
\]

where

\[
\delta = 1/2\sigma^2,
\]

\[
\Delta v_\ell = v_\ell^{\text{obs}} - \bar{v}_\ell,
\]

\[
\Delta v_b = v_b^{\text{obs}} - \bar{v}_b,
\]

\[
C'' = C'\sqrt{\frac{\sqrt{\alpha + \delta}}{\sqrt{\alpha + \delta} - \gamma^2}},
\]

\[
= \frac{\delta}{\sqrt{\pi^2(\alpha + \delta)(\beta + \delta) - \gamma^2}}.
\]

Note that for small error, \(\delta \to \infty\), and equation (A7) reduces to the log of equation (A3) as expected.
