Cavity polaritons are quasi-particles resulting from the strong coupling between a confined electromagnetic field and a material elementary excitation. They are the normal modes of the light-matter Hamiltonian and show a typical energy anticrossing behavior as a function of the energy detuning between the bare photon mode and the material excitation. [1] The minimum energy splitting, measured at resonance, is the so-called vacuum-field Rabi splitting. In 2003, the first observation of intersubband (ISB) polaritons in reflectivity measurements was reported [2], as a result of the coupling between a two-Dimensional Electron Gas (2DEG) excitation and a photon mode in a planar microcavity based on total internal reflection. [3] In the same year, ISB polaritons were also observed in bound to quasi-bound transitions in a quantum well infrared photodetector. [4] Because of the large oscillator strength and of the relative low energy of the ISB transitions, ISB polaritons are good candidates to explore a new regime of light-matter coupling, where the Rabi frequency can be a significant fraction of the transition frequency: the so-called ultra-strong coupling regime. [5] It is predicted that quantum electrodynamics phenomena reminiscent of the dynamic Casimir effect can be observed in this regime. [6, 7] Furthermore, recent works show a growing interest in implementing ISB polaritons in devices [3] and the possibility of electrical control and ultrafast modulation of the ISB strong coupling regime. [8, 10]

In this letter, we report on the experimental observation of ISB cavity polaritons in angle-resolved photovoltaic measurements, performed on a quantum cascade (QC) structure embedded in a planar microcavity (Fig.1). The QC structure is based on a GaAs/Al_{0.45}Ga_{0.55}As heterostructure, grown by molecular-beam epitaxy on an undoped GaAs (001) substrate. The planar microcavity, designed for the confinement of transverse magnetic (TM) polarized radiation, is realized by sandwiching the QC structure between a low refractive index Al_{0.95}Ga_{0.05}As layer and a top metallic mirror. In order to measure the photogenerated voltage, circular mesas of 220 μm diameter are etched down to the bottom n-doped layer just below the active region. Metallic contacts are then provided on the top of the mesa and on the n-doped layer (Fig.1a), so that electrons can be extracted directly from the structure without having to cross the Al_{0.95}Ga_{0.05}As mirror. The sample is soldered onto a copper holder and mounted on the cold finger of a cryostat, cooled at liquid Nitrogen temperature. Angle-resolved measurements are performed by rotating the cold finger in order to probe cavity modes with different energies. The sample facet is polished at 70°, in order to allow a variation of the propagating angle of the incident beam over an angular range (of about 26° internal angle) useful to map the anticrossing curve.

The band diagram of the QC structure, obtained with self-consistent Schrödinger-Poisson calculations, is presented in Fig.1b. Photons confined within the microcavity can be absorbed promoting electrons from level 1 to level 2 of the quantum well (E_{21} = 163 meV), with the consequent creation of ISB excitations in the 2DEG. The electronic band-structure engineering of this QC structure, analogous to that of a quantum cascade detector, [11] is such that electrons preferentially scatter towards one side (left side in Fig.1b) of the quantum well, giving rise to a photovoltage.

In the experiment, the facet of the sample is illuminated with the radiation of a Globar lamp, focused using a f/1.5 ZnSe plano-convex lens. The spectra are collected using a Nicolet Fourier-transform infrared spec-
polarized incident light with a propagating angle of

The arrows represent the optical path of the incident beam. The intensity of the photon mode along the growth axis is sketched (blue curve).

(b) Band diagram of the QC structure. The layer sequence of one period of the structure, in nm, from left to right, starting from the largest well is $6.4/3.6/3.3/1.6/3.2/1.8/2.3/2.0/1.9/2.0/1.8/2.0/2.2/3.9$. $\text{Al}_{0.45}\text{Ga}_{0.55}\text{As}$ layers are in bold, underlined layers are n doped with Si ($3 \times 10^{17}$ cm$^{-3}$). This sequence is repeated 30 times.

detector, in rapid scan mode. The inset of Fig.2 shows three spectra collected with TM-polarized incident light at three different angles, 67.7°, 76.3° and 81.2°. We observe a considerable variation of the shape of the spectra as a function of the angle. In Fig.2 the solid lines are two spectra obtained with TM- and transverse electric (TE) polarized light respectively. The two peaks in dashed lines, labelled $LP$ and $UP$, are the Lorentzian and Gaussian functions, respectively, used in the fitting procedure explained in the text. The result of the three curve fit is shown by the dotted line. Inset: photovoltage spectra with different incident angles (67.7° solid line, 76.3° dotted line, 81.2° dashed line).

FIG. 1: (a) Schematic view of the mesa etched sample. The layers (Si-doping, thickness) from bottom to top are: $\text{Al}_{0.95}\text{Ga}_{0.05}\text{As}$ (undoped, 0.52 μm), GaAs ($3 \times 10^{18}$ cm$^{-3}$, 0.56 μm), QC structure, GaAs ($1 \times 10^{17}$ cm$^{-3}$, 86 nm), GaAs ($3 \times 10^{18}$ cm$^{-3}$, 17 nm), metallic contacts [Ni(10nm)/Ge(60nm)/Au(120nm)/Ni(20nm)/Au(200nm)]. The arrows represent the optical path of the incident beam. The intensity of the photon mode along the growth axis is sketched (blue curve). (b) Band diagram of the QC structure. The layer sequence of one period of the structure, in nm, from left to right, starting from the largest well is $6.4/3.6/3.3/1.6/3.2/1.8/2.3/2.0/1.9/2.0/1.8/2.0/2.2/3.9$. $\text{Al}_{0.45}\text{Ga}_{0.55}\text{As}$ layers are in bold, underlined layers are n doped with Si ($3 \times 10^{17}$ cm$^{-3}$). This sequence is repeated 30 times.

FIG. 2: Normalized photovoltage spectra (spectral resolution of 8 cm$^{-1}$, at 78K) for $\theta = 75^\circ$. The solid lines labelled with TM and TE-ISB represent the spectra collected with TM- and TE-polarized light respectively. The two peaks in dashed lines, labelled $LP$ and $UP$, are the Lorentzian and Gaussian functions, respectively, used in the fitting procedure explained in the text. The result of the three curve fit is shown by the dotted line. Inset: photovoltage spectra with different incident angles (67.7° solid line, 76.3° dotted line, 81.2° dashed line).

To explain our subtracting approach, we concentrate on the TM spectrum of Fig.2. We can distinguish the presence of three peaks: the Lower Polariton ($LP$, dashed line), a middle peak ($TE-\text{ISB}$) and the Upper Polariton ($UP$, dashed line). A three curve fitting procedure using a Lorentzian function (for the $LP$), a Gaussian function (for the $UP$) and the TE-spectrum has been used to identify the height of the $TE-\text{ISB}$ peak. The use of two different functions to obtain the best fit is due to the fact that, for the angle considered (75°), the $LP$ is still more ISB-like and therefore Lorentzian while the $UP$ is still more cavity-like, thus Gaussian. The fitting curve is the dotted line and shows an excellent agreement with the experimental data. Note that the Lorentzian and Gaussian shape swap at resonance in accordance with the light and matter weight of the polaritonic wavefunctions (Fig.3b and c). The result of the fit indicates that...
The area of the spurious $TE - ISB$ peak is $1/3$ of the total area at all angles. This suggests that the bare ISB signal is proportional to the polaritonic contribution, as if it were a consequence of light scattered after polariton absorption.

This observation motivates us to underline the main differences between our experiment and the absorption experiments in which the bare ISB transition is absent.\cite{2, 8} In absorption, the sample is unprocessed and the wavevector of both incident and collected photons are highly selected, by using lenses with long focal length. In our measurements, only the incident angle can be controlled. This implies that all the light undergoing scattering processes within the cavity can contribute to the photovoltaic signal. The reproducibility of our data has been verified on several devices and the presence of the middle peak has been observed also in different processing geometries (ridges of different size). The presence of a third middle peak has already been observed in photoluminescence measurements of exciton polaritons with a fluctuating environment.\cite{13} Further experiments and theoretical investigations are in progress to clearly identify the feature in our system.

In Fig. 3b, the areas of the two polaritonic peaks, normalised to the total area, are plotted as a function of the incident angle: the mixing of the ISB excitation and of the photon mode is evident. As expected, the upper and lower polariton show the same area at zero detuning, when the photonic and the matter fractions are equal. In Fig. 3c, the position of the peaks as a function of the propagating angle (full symbols) is presented, as well as the results of transfer matrix simulations (open triangles). To reproduce the experimental data, in the theoretical calculations, which take into account the dispersion of the refractive index of the Au on the surface (the Ni/Ge/Au alloy has been modeled as Au only), the electronic density has been set to $1$ and the spectra are offset each other for clarity. The dashed lines are guides for the eye. b) Areas of the UP (open symbols) and LP (full symbols) peaks, normalised to the total area, as a function of the internal angle. Squares (circles) represent values obtained using a Lorentzian (Gaussian) function in the fit. c) Energy position of the photovoltage peaks as a function of the incident angle of the radiation (squares for Lorentzian functions, circles for Gaussian functions), compared with the results of the transfer matrix calculations (open triangles). The dashed line shows the energy of the bare ISB transition.
