Abstract. Background/Aim: Differences in risk factors for melanoma between young adults (18-39 years) and middle-aged (40-60 years) are not well documented. In this study, we aimed to determine differences in risk factors and characteristics of melanoma between these groups. Patients and Methods: This retrospective study is a review on 330 patients, including 250 middle-aged and 80 young adults, during the period 2006-2016 in the Tampere university hospital, in Finland. Results: Forty-one per cent of middle-aged and 47% of young adults were defined as higher-risk patients. High nevus count was the most common host risk factor in both groups. Young were more likely to have a family history of melanoma. Middle-aged had more often excessive intermittent sun exposure and a history of sunburn. Conclusion: A high number of patients have host risk factors for melanoma. Several differences exist in risk factors and characteristics of melanomas between young adults and middle-aged patients.

Several host characteristics have been associated with the risk of melanoma. These include the phenotype, the number of nevi, a family history of melanoma (1-3), and the presence of dysplastic nevi (4, 5). Other risk factors include sun exposure and severe sunburns (6). The association of sun exposure with melanoma risk is influenced by host characteristics. In fact, exposure patterns might be of less importance compared to the individual response to sun exposure (6, 7). Differences in melanomas by anatomic site, histology, sex and age, suggest that both host characteristics and behavioral factors influence risk (8). Country-specific variations are related to interactions between sun exposure and skin type, postulated divergent pathways (intermittent vs. cumulative exposure) and critical periods of exposure (6). Sunburn is a stronger predictor compared to intermittent exposure itself (7). Especially sun exposure and sunburn occurrence during childhood are key risk factors for melanoma later in life (9).

There is a large diversity of melanoma across the age spectrum. Melanomas in patients at the extremes of age have a distinct natural history, but there are also differences in characteristics of melanomas within age groups between these extremes (10). In this study, we compared risk factors and characteristics of melanoma in young and middle-aged adults and tried to identify possible differences between these groups. Understanding the risk of melanoma in different age groups and taking into account the country-specific variations is important for the development of effective cancer control activities.

Patients and Methods

New invasive cutaneous melanomas were picked up from the melanoma database at Tampere university hospital (Finland) from 2006 through 2016 using the 3rd-edition of the International Classification of Diseases for Oncology (ICD-O-3) code C43. Patients from 18 to 60 years of age were included in the study. In Finland, 30% of inhabitants have Fitzpatrick’s skin phototypes I or II and 60% have type III (11). All patients in this study had skin types I to III. We ensured that there were no patients duplicated in the study (i.e. with two primary melanomas during the 10-year period of the study).

Permission to access the clinical records was obtained from the scientific center of Tampere University Hospital. The clinical records of all patients were reviewed.
Patients were divided to two age groups: i) younger than 40 years (<40 years) and ii) 40-60 years of age. The location of the tumor was scored: i) trunk, ii) upper limb, iii) lower limb and iv) head and neck. The Breslow thickness (12) reported by a dermatopathologist was recorded. The histological subtypes were classified: i) superficial spreading melanoma (SSM), ii) nodular melanoma (NM), iii) lentigo maligna melanoma (LMM), and iv) acral melanoma (AM). The number of other, biopsy-proven, primary melanomas (OM) and dysplastic nevi (DN) was recorded. Thenevus count, assessed by a doctor during the patient’s first visit in the skin cancer unit, was also recorded. High nevus count (HNC) was defined as having ≥50 nevi.

Information about: i) a history of severe sunburns during childhood (at least two painful sunburns that lasted more than one day), ii) a history of excessive intermittent sun exposure, iii) a family history of melanoma in a first-degree relative (FH), was collected by a doctor after interviewing patients during their first visit to our skin cancer unit.

Statistical analysis. Categorical variables were described by the number of patients with percentages. Differences between categorical variables were tested by Pearson chi-square test, or Fisher’s exact test if Pearson chi-square test assumptions were not valid. Distributions of the skewed continuous variables were tested using the Mann-Whitney test. For multiple comparisons, the Bonferroni correction was performed and p-values under 0.05 as significant. The analyses were carried out using the IBM SPSS Statistics for Windows software, version 23.0 (IBM Corp., Armonk, NY, USA).

Results

A total of 1,248 cases of new invasive cutaneous melanomas were detected in 667 men and 581 women between 1.1.2006 and 31.12.2016. Among these patients, a total of 330 (men: n=150; women: n=180) patients were 60 years of age or younger and were included in the study. Of these patients, 250 were middle-aged (40-60 years) and 80 were young (18-39 years) adults.

Host characteristics, behavioral risk factors and melanoma characteristics for patients <40 years vs. 40-60 years. HNC (26%, 21/80) was the most common host risk factor in the young adults’ group, followed by having DN (20%, 16/80), FH (19%, 15/80) and OM (10%, 8/80) (Table I). In middle-aged group, HNC (28%, 69/250), was also the most common risk factor, followed by DN (24%, 57/250), OM (13%, 32/250) and FH (9%, 22/250). The young patients were, on average, less likely to have excessive intermittent sun exposure (30% vs. 44%, p=0.031) and a history of sunburn in childhood compared to the middle-aged group (25% vs. 43%, p=0.004).

The young group had a higher proportion of SSM (86% vs. 77%, p=0.178), fewer other types of melanomas and thinner (Md Breslow 0.6 mm vs. 1.0 mm, p<0.001) melanomas compare to middle-aged patients. Young were less likely to have a melanoma situated on the trunk (40% vs. 50%) and lower limb (21% vs. 26%) area and more likely to have a melanoma on the upper limb (24% vs. 14%) and head and neck (15% vs. 10%) area (p=0.082). These differences were not statistically significant (Table I).

Discussion

Several findings emerged from this study of 330 young and middle-aged cutaneous melanoma patients. A higher number of patients (41% of middle-aged and 47% of young) were defined as higher risk owing to FH, OM, HNC or DN compared to an earlier study (3), in which 11% of <40 and 33% of 40-59-year-old patients were defined as high-risk patients. This difference may, however, be explained by the different definition of risk factors between studies, as in our study DN was also counted in. The problem in comparing findings from the literature, is that, according to our knowledge, there are only a few studies which compare risk factors for melanoma in young and middle-aged adults.

The ratio of patients with FH is in agreement with other studies, but findings differ with regards to age distribution (8, 13, 14). In our study, young adults were more likely to have FH compared to middle-aged, while in other studies patients older than 40 years were more likely to have FH. Whether this difference can be explained by country-specific variations in the population remains unclear. Different results have also been observed between studies concerning the Breslow thickness of melanomas in patients with FH. Li et al. (8), have found that individuals with FH might be more likely to develop thicker melanomas, while Chiarugi with coworkers (14) did not find differences in thickness between familiar and sporadic melanomas. We found that a majority of patients with FH had thin melanoma, which is in...
agreement with the study by Aguilera and cowriters (13). This finding suggests that melanoma patients with FH may have an increased risk awareness and could benefit from an early detection of melanoma.

A high number of nevi is the most significant phenotypic risk factor for melanoma and is in part genetically determined (15). Having HNC was the most common host risk factor for melanoma in both young and middle-aged adults. In these patients, melanomas were more likely thin and located in the trunk area, confirming data from previous melanoma studies (4, 15). It has been suggested that individuals with HNC may be more likely to practice skin self-examination, which may lead to an earlier detection of melanoma (4). There is also a possibility that the genetic determinants of nevi number may be associated with biological differences in melanoma tumors (15). Most patients with melanoma, however, did not have HNC. The total nevus count should not be the only reason for performing a skin examination or determining a patient’s risk-status.

Table I. Descriptive statistics for risk factors and characteristics of melanoma according to age group in all melanomas included in the study (n=330).

| Risk Factor                                                | <40 years (n=80) | 40-60 years (n=250) | p-Value |
|-----------------------------------------------------------|------------------|----------------------|---------|
| Gender, n (%)                                             |                  |                      | 0.008   |
| Male                                                      | 26 (33)          | 124 (50)             |         |

High-risk patients: Hight nevus count, family history, other melanomas and/or dysplastic nevus; Years: age at the time of diagnosis; Md: median; IQR: interquartile range. Differences between age-groups were analyzed using Mann-Whiney test (continuous, but skewed factors), Pearson chi-square test or Fisher’s exact test, if Pearson chi-square test assumptions were not valid (categorical factors).
Melanomas in patients with DN were more likely to be thinner and presented more commonly in middle-aged patients; observations adding support to prior studies (4, 5). The subtype of melanomas, however, differed between studies. In our study, melanomas in patients with DN were less likely to be SSM and more likely NM compared to patients without DN or other host risk factors. In other studies, SSM was a more common subtype and NM less frequent one in patients with DN compared to patients without DN (4, 5). SSM is considered to be less aggressive and is more often detected as a thinner tumor with a slower growth compared to NM (16).

The proportion of patients with biopsy-proven OM was higher here (11%) compared to previous studies with regards to all age groups (1.2-8.2%) (17-19). The reason for this difference between studies is not clear, however, one reason may be the different age groups studied. In our study, only patients 60 years or younger were included. In prior studies, OM were diagnosed in patients with different predominance on gender and age. Observations supporting both males of an older age (17) and females of an early age (19) have been published. In our study, OM were more likely diagnosed in the middle-aged group with female predominance. Even one tenth of ≤60-year-old melanoma patients developed a second primary melanoma. Careful education of melanoma patients could facilitate an earlier diagnosis of a subsequent second primary melanoma.

When comparing behavioral risk factors, we observed that young adults had less excessive sun exposure during adulthood and a history of sunburn during childhood compared to middle-aged patients. It has been suggested in earlier studies that public health campaigns promote

| Subtype | FH (n=37) | No FH (n=293) | HNC (n=90) | No HNC (n=240) | OM (n=40) | No OM (n=290) | DN (n=75) | No DN (n=255) |

awareness of the risk of sun exposure in Australia and Europe and may have contributed to stabilizing or declining the melanoma incidence rates in young adults (1). Whether this is true also in our population remains to be studied. In this study, over one third of the patients with high-risk host characteristics had a history of excessive intermittent sun exposure or a history of sunburns during childhood. Similar results have been previously reported by Chiarugi et al. (14) in patients with FH. This finding suggests that patients with high risk characteristics are not careful enough to prevent melanoma. Continued close monitoring and information about sun protection of high-risk population is necessary.

We acknowledge several limitations in our study. First, certain subgroups are limited by the small numbers of patients. The disproportion between the two age groups of the study, can be explained by the different distribution of melanoma depending on age but can still limit the interpretation of the results. Second, this study is limited to studying patients at an academic center rather than from a cohort of a wider population. Despite this limitation, our patients were referred from surrounding regions as well. Third, the familial status was based on patients’ self-reported family history. To minimize the risk of recall we applied the criteria with no more distance than the first-degree relatives. Fourth, skin cancer patients may overreport or underreport their sunburn or sun exposure experience, producing biased estimates of the true association. On the other hand, the majority of studies use verbal reports or self-reports to measure habitual sun exposure. Despite well-known limitations of verbal reports, these measures were suggested to be the most practical for both population surveillance and intervention research (20).

We think that these results lead to some scientific and health educational suggestions. Our findings support prior studies, while also offering distinct new information about melanomas in a different country-specific population. The findings from this study may help identify strategies to further stratify patients for more targeted patient education and potential screening.

In conclusion, young and middle-aged adults have differences in risk factors for melanoma. Our data support more intensive skin cancer screening for patients of 60 years of age or younger with DN. The characteristics of melanomas in higher-risk patients in our study population have some differences compared to the characteristics described in earlier studies, supporting the existence of country-specific variations in melanomas. Characterization of these features may assist in understanding of heterogeneity of melanoma and targeting country-specific cancer treatment and control activities.

Conflicts of Interest

The Authors declare that they have no conflicts of interest.

Authors’ Contributions

Writing and acquisition of data: Palve J; Analysis and interpretation of data: Palve J and Luukkaala T; Review and revision of the manuscript: Korhonen N and Kääriäinen M.
