Abstract

We consider decaying dark matter with masses $10^7 \lesssim M \lesssim 10^{16}$ GeV, as a source of ultra-high energy (UHE) gamma rays. Using recent limits on UHE gamma-ray flux for energies $E_\gamma > 2 \cdot 10^{14}$ eV, provided by extensive air shower observatories, we put limits on masses and lifetimes of the dark matter. We also discuss possible dark matter decay origin of tentative 100 PeV photon flux detected with EAS-MSU experiment.

Keywords: superheavy dark matter, cosmic rays.

1 Introduction

One of the candidates for the role of dark matter are superheavy particles [1,2] (see also Ref. [3,4]), that we will denote as $X$ particles. From the point of view of particle physics they can be incorporated into various theories (see e.g. Ref. [5,6] and references therein). In cosmology these particles could be created at some early stages of the Universe evolution [1,2,5–10]. In this paper we consider indirect detection of superheavy dark matter (SHDM). The parameters that can be experimentally constrained in this approach are mass, annihilation cross-section and lifetime of the dark matter particles. While there are several constrains on $X$ particles mass $M_X$ imposed by various scenarios of the dark matter production [5,10,13], in this study we conservatively consider the full range of $M_X$ accessible for indirect observation in recent high energy cosmic ray experiments, namely: $10^7 \lesssim M_X \lesssim 10^{16}$ GeV. The detection of the annihilation signal of particles with these masses is far beyond reach of the modern experiments because of the unitarity bound on the $X$ particles annihilation cross-section [16]: $\sigma_{\text{ann.}} \sim 1/M_X^2$. Therefore, in this work we are focusing on the case of decaying DM with long lifetime $\tau \gg 10^{10}$ yr.

∗mkuzn@inr.ac.ru
Modern cosmic ray experiments allow to study primary particles composition based on observed extensive air showers (EAS) properties. The spectrum of protons and nuclei with $E > 100$ TeV has been studied in detail in several experiments. In contrast only upper limits on gamma ray fluxes in the same energy range have been obtained so far. In this paper we are using these limits to build constraints on decaying SHDM. For the highest energy ($E \gtrsim 10^{18}$ eV) the recent constraints on gamma ray flux are given by Pierre Auger Observatory [31,32], Telescope Array experiment [33] and Yakutsk experiment [34]. Among the constraints of lower energy gamma flux are the results of KASCADE-Grande [39], KASCADE [36] and CASA-MIA [35].

The main motivation for this study is to refine constraints on SHDM parameters using all currently available experimental data. For previous works on the same subject see e.g. [16,42,44]. In recent years the interest to the subject has grown [43,45,46,48] due to PeV neutrino events observation by IceCube [40].

This paper is organized as follows. In Sec. 2 we briefly review SHDM decay physics, consider assumptions about source distribution and propagation of photons in cosmic medium and calculate photon flux from the decay of SHDM. In Sec. 3 we compare our results with existing limits on high energy photon flux and constraint SHDM mass and lifetime.

2 Gamma-ray flux from SHDM decay

The decay of super-heavy particles $X$ was in detail studied in several works [14,15,17,19]. In this work we concentrate on QCD decay channels, since in this case relatively large flux of photons is produced which makes them easier to constrain with experimental photon flux limits. Note that other decay modes (i.e. leptonic) may also lead to some photon flux either via direct gamma production or by means of interactions of products (i.e. electrons) with cosmic microwave background (CMB) and galactic media. Though these channels may be important only if QCD decay is relatively suppressed. For a review of various DM decay modes see Ref. [49].

We consider the two-body decay into quark–antiquark or gluon-gluon pair. The following QCD cascade develops down in energy until the hadronization occurs. As a result of hadronization and subsequent decay of unstable hadrons particles such as protons, photons, electrons and neutrinos are produced. It is important to note, that the impact of electroweak interactions on the hadronic decay channels is subdominant with respect to other uncertainties of this calculation (e.g. the choice of fragmentation functions, see below). For low $M_X$ — low energy region we validate this assumption comparing the decay spectra of Refs. [49,50] with and without EW corrections. For high $M_X$ and high energies we compare the spectra obtained in Ref. [18,19], where full MSSM was considered, with that of Ref. [15], where authors considered only SUSY QCD interactions. In both energy regions the difference was found negligible.

In some earlier works (see e.g. Ref. [42]) the observed shape of proton spectrum was also used to constrain the SHDM parameters. This method gives weaker results than the usage of $\gamma$–limits since the proton flux is dominated by the particles of astrophysical

---

1) We should also mention a tentative result of primary gamma detection in EAS-MSU experiment [37,38].
origin. Therefore in this study we do not consider proton flux from SHDM decay.

Technically the spectra of the $X$-particle decay is defined similarly to the spectra of $e^+e^- \rightarrow \text{hadrons}$ process [20]:

$$F^h(x, s) = \sum_i \int \frac{dz}{z} C_i(z, \alpha_s(s)) D^h_i(x/z, s)$$

(1)

where $x \equiv \frac{2E}{M_X}$ is the energy of hadron as a fraction of the total available energy, $D^h_i(x, s)$ are the fragmentation functions of hadron of the type $h$ from the parton of the type $i$, $C_i(z, \alpha_s(s))$ are the coefficient functions and the summation goes over all types of partons $i = \{u, \bar{u}, d, \bar{d}, ..., g\}$. The normalization to the $X$ particle decay width is assumed. For the leading order in $\alpha_s$ the coefficient functions $C_i$ are proportional to $\delta(1 - z)$ and the total spectrum is equal to the sum of fragmentation functions $F^h(x, s) = \sum_i D^h_i(x, s)$.

Given the fragmentation function at some scale $s$ we can evolve it to another scale using DGLAP equations [21, 22]:

$$\frac{\partial D^h_i(x, s)}{\partial \ln s} = \sum_j \frac{\alpha_s(s)}{2\pi} P_{ij}(x, \alpha_s(s)) \otimes D^h_j(x, s),$$

(2)

where $\otimes$ denotes the convolution $f(x) \otimes g(x) \equiv \int_x^1 dz/z f(z) g(x/z) = \int_x^1 dz/z f(x/z) g(z)$ and $P_{ij}(x, s)$ is the splitting function for the parton branching $i \rightarrow j$. Since we study the process on the scale $M_X \gg m_q$ we assume all $N_f$ quark flavors are coupled to gluon similarly and we can confine ourselves to considering only the mixing of gluon fragmentation function with a quark singlet fragmentation function:

$$D^h_q(x, s) = \frac{1}{N_f} \sum_{i=1}^{N_f} [D^h_{qi}(x, s) + D^h_{q\bar{i}}(x, s)].$$

(3)

Then DGLAP equations take the form:

$$\frac{\partial}{\partial \ln s} \left( \begin{array}{c} D^h_q(x, s) \\ D^h_{\bar{q}}(x, s) \end{array} \right) = \left( \begin{array}{cc} P_{qq}(x, s) & P_{q\bar{q}}(x, s) \\ 2N_f P_{q\bar{q}}(x, s) & P_{\bar{q}\bar{q}}(x, s) \end{array} \right) \otimes \left( \begin{array}{c} D^h_q(x, s) \\ D^h_{\bar{q}}(x, s) \end{array} \right).$$

(4)

In this study we use the code kindly provided by the authors of Ref. [15]. This code evaluates the DGLAP equations numerically in the leading order in $\alpha(s)$. We use the initial fragmentation functions from the Ref. [20] parametrized on the scale $M_Z$ and extrapolated to the region $10^{-5} \leq x \leq 1$. Although the low $x$ tail is unreliable at this scale, the results obtained for the high scales $M_X$ agree with that obtained by Monte-Carlo simulation, as it was shown in [15]. Fortunately, the spectra calculated in this region of $x$ are enough to constrain the results with the experiment in the mass range of interest: $10^7 \leq M_X \leq 10^{16}$ GeV. In this paper we calculate only prompt photon spectra of $\pi^0$s decay and neglect the smaller amount of photons from inverse Compton scattering (ICS) of prompt $e^\pm$ on the interstellar background photons. While for the leptonic decay channels the relative contribution of inverse Compton photons to the full spectrum can be significant [46], for hadronic channels it is at least by order of magnitude lower [49], so we neglect the contribution from prompt $e^\pm$ via ICS in this study. Following [15] we...
also neglect roughly 10% contribution of other mesons decay. Then the photon spectrum of the $X$–particle decay is given by:

$$D^\gamma(x) = 2 \int_x^1 \frac{dz}{z} D^\pi^0(z),$$

(5)

where $D^{\pi^0}(x, s) \equiv [D^{\pi^0}_q(x, s) + D^{\pi^0}_g(x, s)]$. The examples of prompt photon spectra for decay of $X$–particle with different masses are shown in Fig 1.

Having the injected photon spectra we can calculate the corresponding photon flux reaching the Earth. We use the following assumptions. First of all we neglect the flux coming from extragalactic region. Starting at $E_\gamma = 2 \cdot 10^{14}$ eV, which is the lowest energy where the EAS experiments provide photon limits, and up to $E_\gamma \simeq 2 \cdot 10^{18}$ eV the photon attenuation length doesn’t exceed the size of our Galaxy halo. Then, up to the highest experimentally tested energy $E_\gamma = 10^{20}$ eV photons can come from a region of size not exceeding 50 Mpc, which contribution to the flux is about 1% of that from our Galaxy.

For the galactic photon flux calculation we use Navarro-Frenk-White dark matter distribution \cite{24,25} with the parametrization for Milky Way from Ref. \cite{49}. We assume photons being radiated isotropically in the decay of $X$–particle. As it was mentioned above, for photons with $E \gtrsim 10^{18}$ eV the attenuation length in interstellar medium exceeds the size of our Galaxy halo. This implies that for higher energy photon we can neglect the absorption and cascaded radiation. Indeed, the comparison of the non-interacting and cascading $\gamma$ fluxes from our Galaxy (the latter was calculated using the numerical code from Ref. \cite{27}, see below ) shows that the discrepancy does not exceeds

\[^2\) For comparison we have also tested Burkert dark matter profile \cite{26}.

Figure 1: Prompt photon spectra of $X$–particle decay.
few percent for $E = 10^{18}$ eV (see Fig. 2). Therefore we neglect the photon interaction with the medium for $M_X \gtrsim 10^{14}$ GeV. Using the above assumptions we obtain the following expression for the integral photon flux received by a given cosmic ray observatory:

$$F(E > E_{\text{min}}) = \frac{N(E > E_{\text{min}})}{4\pi M_X \tau} \cdot \frac{\int \frac{\rho(R)\omega(\delta, a_0, \theta_{\text{max}})}{r^2} dV}{2\pi \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \omega(\delta, a_0, \theta_{\text{max}}) \cos(\delta) d\delta};$$  \hspace{1cm} (6)

where $\rho(R)$ — is a DM density as a function of distance $R$ from galactic center, $r$ — is a distance from Earth, $\omega$ — is a relative exposure of the given observatory and $N(E > E_{\text{min}})$ — is an integral number of photons with energies higher than $E_{\text{min}}$ produced in the decay of $X$–particle. Integration in the numerator takes over all volume of halo ($R_{\text{max}} = 260$ kpc) and in the denominator over all sky (the averaging over right ascension is included in the definition of $\omega$). The relative exposure $\omega$ is a function of declination $\delta$, geographical latitude of the given experiment $a_0$ and the maximal zenith angle $\theta_{\text{max}}$ of particles allowed for observation in this experiment (see Refs. [28,29] for details).

For $M_X \lesssim 10^{14}$ GeV we also take into account the attenuation of photons on CMB using the numerical code [27]. The code simulates development of electron-photon cascades on CMB driven by the chain of $e^\pm$ pair production and inverse Compton scattering. Although the code allows to calculate the flux of the cascade photons it doesn’t take into account deflections of $e^\pm$ by the halo magnetic field. Since electrons in the code propagate rectilinearly they produce less cascade photons. Therefore the calculated flux of photons should be considered as conservative lower bound. The propagation code [27] also includes attenuation of photons on extragalactic background light (EBL), though the effect of EBL is negligible on distances which we consider.

### 3 Comparison with photon limits

Finally we compare the predicted SHDM signal with the existing experimental upper-limits on photon flux. For the highest observable cosmic ray energies ($E_{\text{CR}} \gtrsim 10^{18}$ eV) the recent constraints are provided by Pierre Auger Observatory [31,32], Telescope Array experiment [33] and Yakutsk experiment [34], while for the lower energies we use the results of CASA-MIA [35], KASCADE [36], KASCADE-Grande [39] and EAS-MSU [38]. For a review of experimental results see e.g. Ref. [30] and references therein. We should note, that the higher energy limits are more effective for constraining SHDM since its decay spectra is quite hard, i.e. SHDM photon flux grows slower than the experimental limits with the decreasing of energy.

Another possible contribution to UHE photon flux comes from astrophysics. UHE protons and nuclei produced by extragalactic sources interact with CMB and other interstellar background producing secondary electron-photon cascades and neutrinos. The essentially isotropic flux of photons of this origin has been estimated in several scenarios including proton and nuclei emitting sources (see e.g. Refs. [51–55]). Contrary to the astrophysical signal the SHDM contribution is anisotropic with maximum flux arriving from the center of Milky Way. In Figs. 3–4 we show the $\gamma$–ray flux limits by KASCADE,
Figure 2: Integral photon flux from SHDM decay in our Galaxy halo as received by Telescope array experiment, $M_X = 10^{12}$ GeV, without interactions of photons with medium (solid line), with photon interactions with CMB and secondary cascade radiation included (dashed curve).

Figure 3: Predicted integral photon flux from decay of SHDM with mass $M_X = 10^{14}$ GeV and lifetime $\tau = 2 \cdot 10^{22}$ yr compared with upper–limits of Pierre Auger Observatory [31, 32] and its estimated sensitivity for 2020 (assuming the upgrade of facility) [30]. Estimates of $\gamma$–ray background produced by attenuation of UHE protons [51] (green shaded) and UHE protons and iron induced cascades [52] (blue and orange shaded) are shown with their theoretical uncertainties.
Figure 4: Predicted integral photon flux from decay of SHDM with mass $M_X = 10^9$ GeV and lifetime $\tau = 3 \cdot 10^{21}$ yr compared with upper limits of KASCADE and KASCADE-Grande experiments \cite{36,39}, estimated sensitivity of Carpet 2+ experiment \cite{41} and the estimate \cite{53} of $\gamma$ background from pp–interactions in halo.

KASCADE-Grande and Pierre Auger Observatory together with predicted SHDM decay photon flux (for certain parameters of SHDM) and some estimates of astrophysical photon flux. Also we show the estimated future sensitivity of Carpet experiment \cite{41} in Fig. 4 and upgraded PAO \cite{30} in Fig. 3.

We compare the constraints of various experiments on SHDM mass and lifetime in Fig. 5. The constraints are built by scanning SHDM parameter space and matching the predicted photon signal with the limits of the given experiment. The model is considered as excluded as soon as the signal touches the limit points from below. For EAS-MSU result of photon detection \cite{38} we show the fit assuming the whole photon flux being produced by SHDM decay. The constraints based on Pierre Auger Observatory limits are the strongest since this experiment has largest exposure among UHECR experiments and it is located in the Southern hemisphere where higher $\gamma$-ray flux coming from galactic center could be detected. The strongest constraint over all mass range is $\tau \gtrsim 3 \cdot 10^{22}$ yr at $M_X \simeq 3 \cdot 10^{12}$ GeV. It slightly improves the result of Ref. \cite{43} for which the old PAO limits were used. In the low energy region the best constraints are derived from KASCADE, CASA-MIA and KASCADE-Grande: minimal lifetime increases from $\tau \simeq 6 \cdot 10^{19}$ yr at $M_X = 10^7$ GeV to $\tau \simeq 3 \cdot 10^{21}$ yr at $M_X = 5 \cdot 10^9$ GeV being of the same order as the constraints of Refs. \cite{44,46} that were obtained in a wider theoretical context. The constraints obtained with Burkert dark matter profile is slightly weaker than that of NFW in the high energy region, where PAO observes the Galactic center, and stronger.

\footnote{Because of the strong anisotropy of the predicted SHDM signal, we do not show all the existing experimental limits on single picture. KASCADE and Carpet experiments have approximately the same geographical latitude.}
Figure 5: Constraints on mass $M_X$ and lifetime $\tau$ of super heavy dark matter. White area is excluded. For comparison we present the constraints obtained with Burkert DM profile (solid thin red line). We also show the constraint obtained with neutrino limits: for $X \rightarrow \nu\bar{\nu}$ channel [47] (blue dots) and for $X \rightarrow b\bar{b}$ channel [44] (black dots).

for low energies, where constraints are put by Northern hemisphere experiments.

It is also interesting to compare our constraints with those obtained from neutrino limits. In Ref. [44] the neutrino constraints on $\tau$ was imposed for $M_X < 10^{10}$ GeV and for various decay channels. Our constraints are of the same order as these for $M_X \gtrsim 10^9$ GeV but become weaker for $M_X \lesssim 10^9$ GeV. The case of direct decay of dark matter into neutrino was studied in Ref. [47] for a wide region $10 < M_X < 10^{19}$ GeV. The constraints on $\tau$ obtained there are of the same order as ours for $M_X \gtrsim 10^8$ GeV and weaker for all higher masses.

Our constraints have implication for the EAS-MSU tentative result of 100 PeV gamma detection [38]. We may see that the curve interpreting it as the product of SHDM decay lies deep in the parameter area excluded by the other experiments, this implies that SHDM component in EAS-MSU photon signal can not be dominant.

Discussing these results we may note that although the recent experimental limits touch the astrophysically predicted region, due to large uncertainty of astrophysical $\gamma$-ray flux, one can not yet exclude the dominant contribution of SHDM decay. Nevertheless, one might use the guaranteed i.e. minimal predicted astrophysical gamma flux to constrain SHDM parameters even stronger. Finally, if $\gamma$-rays are detected the discrimination between the astrophysical and the SHDM (or other exotic) origin scenario could be in principal made by analysing the flux anisotropy and energy spectrum.
Acknowledgements

We thank S. Troitsky and G. Rubtsov for helpful discussions. We are especially indebted to R. Aloisio, V. Berezinsky and M. Kachelriess for providing the numerical code solving DGLAP equations. This work has been supported by Russian Science Foundation grant 14-22-00161. Numerical simulations have been performed in part at the computer cluster of the Theoretical Physics Department of the Institute for Nuclear Research of the Russian Academy of Sciences.
