PROBING NEW GAUGE BOSON
COUPLINGS VIA THREE-BODY DECAYS

ABSTRACT

We examine the possibility of using rare, 3-body decays of a new neutral gauge
boson, $Z_2$, to probe its gauge couplings at hadron colliders. Specifically, we study
the decays $Z_2 \rightarrow W\ell\nu$ and $Z_2 \rightarrow Z\nu\bar{\nu}$ and find that much knowledge of the $Z_2$
properties can be obtained from these processes. In particular, these decay modes
can yield valuable information on the amount of $Z_1 - Z_2$ mixing, on the generation
dependence of the $Z_2$ couplings, on the properties of the new generator associated
with the $Z_2$, as well as being used to distinguish between possible extended
models. The analogous 3-body decays into a new, heavy charged gauge boson,
$Z_2 \rightarrow W_2^\pm \ell\mp \nu$, are also investigated in models where this can occur.

It is now commonly accepted that if a new neutral gauge boson \((Z')\) exists, it should be observed by direct production, via \(pp \rightarrow Z' \rightarrow \ell^+\ell^-\), at both the SSC and LHC supercolliders if its mass is of order a few TeV or less\(^1\) (provided it couples to both \(q\bar{q}\) and \(\ell^+\ell^-\) pairs at or near electroweak strength). Indeed, if a \(Z'\) is discovered we will want to learn as much about it as possible, in particular, the next logical step would be to determine its gauge couplings and the extended model that bears it origin. Unlike \(e^+e^-\) machines, hadron colliders are limited to only a few measurable quantities with which the new gauge boson properties can be determined. In addition to obtaining the \(Z'\) mass, the planned SSC and LHC detectors\(^2\) will be able to collect data on the \(Z'\) production cross section and subsequent decay into \(\ell^+\ell^-\), the full \(Z'\) width, and the leptonic forward-backward asymmetry. Unfortunately, these measurements will not only be statistics limited but also will experience reasonably large systematic effects due to finite mass resolution and efficiencies as well as uncertainties in the collider luminosity. To further extract coupling information, uncertainties in the parton distributions will also contribute to the systematic errors. If, however, several theoretical assumptions are made, one can use the above data to distinguish new \(Z'\) bosons from different models with reasonable reliability\(^3\).

In order to obtain more and better information on \(Z'\) couplings, we need an additional set of quantities, which do not suffer the large theoretical or systematic uncertainties discussed above, can be measured with reasonable statistics, and yet are sensitive to the particular extended model. Since decay modes involving leptons provide the cleanest signatures and the conventional \(\ell^+\ell^-\) mode is already being used to discover the \(Z'\), one of the next possibilities to consider are various three-body decays. One potential process\(^4\), which has recently been revived\(^5\), is to look
for the decay $Z' \to W^{\pm} \ell^{\mp} \nu$, and, in particular, to measure the ratio

$$r_{\ell\nu W} = \frac{\Gamma(Z' \to W^{\pm} \ell^{\mp} \nu)}{\Gamma(Z' \to \ell^{+} \ell^{-})},$$  \hspace{1cm} (1)$$

which suffers very little from the above mentioned systematic uncertainties. (We note that in this definition of $r_{\ell\nu W}$ we sum over both $W^{\pm}$ modes, but there is no sum over $\ell$ which we assume to be either $e$ or $\mu$.) A second such useful quantity$^5$ is the corresponding ratio

$$r_{\nu\nu Z} = \frac{\Gamma(Z' \to Z_{\nu} \bar{\nu}_{\ell})}{\Gamma(Z' \to \ell^{+} \ell^{-})},$$  \hspace{1cm} (2)$$

wherein a sum over the three generations of $\nu$ is assumed. If one allows for decays of the $Z'$ into two jets plus a $W^{\pm}$ or $Z$, two additional quantities can be defined which parallel $r_{\ell\nu W}$ and $r_{\nu\nu Z}$ above. We feel, however, that though $W^{\pm}$ or $Z+$ jets final states from $Z'$ decay might be separable from Standard Model (SM) backgrounds, these modes will no longer be as clean as the two discussed above. Thus we restrict our attention to $r_{\ell\nu W}$ and $r_{\nu\nu Z}$ below, where we will find that measurements of these two quantities will reveal much about the nature of the $Z'$.

We first examine the process $Z' \to W^{\pm} \ell^{\mp} \nu$ and the ratio $r_{\ell\nu W}$. In general, as discussed in Ref. 4, this reaction can proceed either by $W$ emission off of a fermion leg, or via a $Z'W^+W^-$ coupling which exists only if the $Z'$ mixes with the SM $Z$. The Feynman diagrams responsible for these contributions are displayed in Fig. 1. If $Z - Z'$ mixing is non-vanishing, then both the $Z$ and $Z'$ are not mass eigenstates. The physical states will then be

$$Z_2 = Z' \cos \phi - Z \sin \phi,$$

$$Z_1 = Z' \sin \phi + Z \cos \phi,$$  \hspace{1cm} (3)$$

with the state $Z_1$ being the one probed at LEP, and $Z'(Z)$ must be replaced by
In the discussion above. We emphasize that the $Z_2 W^+ W^-$ coupling only occurs via this mixing. Following Ref. 4 and Marciano and Wyler, we can then write the quantity $r_{\ell \nu W}$ as

$$r_{\ell \nu W} = \frac{G_F M_W^2}{2\sqrt{2} \pi^2} (v_{2\ell}^2 + a_{2\ell}^2)^{-1} \left\{ \begin{array}{c} \frac{1}{2} [(v_{2\ell} + a_{2\ell})^2 + (v_{2\nu} + a_{2\nu})^2] H_1 \\ + (v_{2\ell} + a_{2\ell})(v_{2\nu} + a_{2\nu}) H_3 \\ + \frac{1}{2} (s_\phi c_w^2) H_2 \\ - s_\phi c_w^2 [(v_{2\ell} + a_{2\ell}) - (v_{2\nu} + a_{2\nu})] H_4 \end{array} \right\}, \quad (4)$$

where the $v'$s and $a'$s represent the various vector and axial vector couplings of the $Z_2$ to charged leptons and neutrinos, $s_\phi = \sin \phi$, and $c_w = \cos \theta_w$, with $x_w = \sin^2 \theta_w$. Note that the last two terms in this expression are proportional to the amount of $Z - Z'$ mixing and arise from the diagram of Fig. 1c. The quantities $H_i$ are the results of performing one dimensional integrations over modified forms of the functions given in Ref. 6. These modifications arise for $H_{2,4}$ only (the terms that arise from the $Z_2 W^+ W^-$ coupling), since we must now integrate over the $W$-resonance requiring that the finite $W$-width, $\Gamma_W$, be included in the calculation. This was not included in the analysis of Ref. 6 since both of the $W'$s could not be on-shell simultaneously as $M_Z < 2M_W$. Thus the $H_i$ functions depend only on $M_W$, $\Gamma_W$, and the $Z_2$ mass, $M_2$. Clearly, $r_{\ell \nu W}$ will be quite sensitive to $s_\phi \neq 0$; when $s_\phi = 0$, only the above terms with $H_{1,3}$ will remain. For the moment, we will assume that $s_\phi = 0$, and will neglect any possible influence from $W - W'$ mixing. In Fig. 2 we present the number of events expected per year at the SSC with an integrated luminosity of $10^4$ pb$^{-1}$ from the process $pp \rightarrow Z_2 \rightarrow W^\pm \ell^\mp \nu$ as a function of the $Z_2$ mass for various extended models, which are discussed below.
We see that hundreds of events are expected for $Z_2$ masses up to $\sim 2$ TeV in most models. Here we have included a lepton identification efficiency of $\epsilon = 85\%$ for each lepton.

Since it is assumed that a $Z_2$ exists, it must couple to a new diagonal generator, $D$, originating from an extended gauge group. If $D$ and the ordinary $SU(2)_L$ generator $T_{iL}$ commute, i.e., $[D, T_{iL}] = 0$, or if only

$$[D, T_{iL}]| \nu_L, \ell_L >= 0$$

is satisfied, then $v_{2\ell} + a_{2\ell} = v_{2\nu} + a_{2\nu}$ and $r_{\ell\nu Z}$ simplifies to

$$r_{\ell\nu W} = \frac{G_F M_Z^2}{2 \sqrt{2} \pi^2} \sqrt{(H_1 + H_3)(v_{2\ell} + a_{2\ell})^2(v_{2\ell}^2 + a_{2\ell}^2)^{-1}}. \quad (4')$$

Note that Eq. (4') can never be satisfied when $s_\phi \neq 0$ since $D$ will then contain the term $-s_\phi(T_{3L} - x_w Q)$ and neither $Q$ nor $T_{3L}$ commutes with $T_{1,2L}$. We will return to Eqs. (4-5) after a brief discussion of $r_{\nu\nu Z}$.

Let us also examine the ratio $r \equiv \Gamma(Z_2 \to Z_1 f \bar{f})/\Gamma(Z_2 \to \ell^+ \ell^-)$, which is given by

$$r = \frac{G_F M_Z^2}{8 \sqrt{2} \pi^2} N_c N_f \left( v_{1f} + a_{1f} \right)^2 \left( v_{2f} + a_{2f} \right)^2 + \left( v_{1f} - a_{1f} \right)^2 \left( v_{2f} - a_{2f} \right)^2 \left( v_{2\ell} + a_{2\ell} \right)^2 \left( v_{2\ell}^2 + a_{2\ell}^2 \right)^{-1} I, \quad (6)$$

where $N_c$ is the usual color factor, $I$ is a two-dimensional parameter integral which depends only on $M_1^2/M_2^2$ (when fermion masses are neglected), and $N_f$ labels the number of flavors of a given type. For three generations of left-handed neutrinos, $N_c = 1$, $N_f = 3$, $v_{1\nu} = a_{1\nu}$, and $v_{2\nu} = a_{2\nu}$ so that

$$r_{\nu\nu Z} = \frac{3G_F M_Z^2}{2 \sqrt{2} \pi^2} \frac{4v_{1\nu}^2 v_{2\nu}^2}{(v_{2\ell}^2 + a_{2\ell}^2)} I. \quad (7)$$

Here we have assumed that all the various couplings are generation independent in performing the sum over $\nu_e$, $\nu_\mu$, and $\nu_\tau$. Note that with our normalization
convention, $4v_{12}^2 = 1$ when $s_\phi = 0$. We anticipate that, unlike $r_{\ell\nu W}$, $r_{\nu\nu Z}$ will not be greatly affected by $s_\phi \neq 0$; we will see further below that this is the case. For now, we continue to assume that $s_\phi = 0$ and also take Eq. (4') to be valid, we then see that

$$r_{\nu\nu Z} = K_Z \frac{v_{2\nu}^2}{v_{2\ell}^2 + a_{2\ell}^2}. \quad (8)$$

and, using the fact that $v_{2\nu} + a_{2\nu} = v_{2\ell} + a_{2\ell}$ together with $a_{2\nu} = v_{2\nu}$ we find

$$r_{\ell\nu W} = K_W \frac{v_{2\nu}^2}{v_{2\ell}^2 + a_{2\ell}^2}, \quad (9)$$

Here $K_{W,Z}$ are functions of the gauge boson masses only, $(M_2, M_W, and M_1)$ and are independent of the choice of extended electroweak model. Thus, if the above conditions hold, all predictions for $r_{\nu\nu Z}/r_{\ell\nu W}$ must lie on a straight line, i.e.,

$$\frac{r_{\nu\nu Z}}{r_{\ell\nu W}} = \frac{K_Z}{K_W}. \quad (10)$$

Furthermore, Eqs. (8) and (9) tell us that both $r_{\nu\nu Z}$ and $r_{\ell\nu W}$ are bounded

$$0 \leq r_{\ell\nu W} \leq \frac{1}{2} K_W,$$

$$0 \leq r_{\nu\nu Z} \leq \frac{1}{2} K_Z, \quad (11)$$

with the lower (upper) end-points of these ranges occurring for a purely right-handed (left-handed) $Z_2$ coupling to leptons. Thus not only is the ratio $r_{\nu\nu Z}/r_{\ell\nu W}$ model independent, but the value of the quantities themselves are restricted to a small region of the $r_{\nu\nu Z} - r_{\ell\nu W}$ plane, with both being dictated solely by the values of $M_{1,2}$ and $M_W$. In addition, the position of the measured values of $r_{\nu\nu Z}$ and $r_{\ell\nu W}$ along the line will yield information on the ratio of the vector and axial-vector couplings of the $Z_2$, up to a two-fold ambiguity, $v_\ell \leftrightarrow a_\ell$. 
As an application of these results, we now examine the $r_{\nu\nu Z} - r_{\ell\nu W}$ plane for some of the more well-known extended gauge models, taking $M_2 = 1$ TeV for purposes of demonstration. We also use $M_1 = 91.175$ GeV, $M_W = 80.14$ GeV, $\Gamma_W = 2.15$ GeV (Ref. 7), and $x_w = 0.2330$ in our numerical analysis below. We stress that all these results assume $s_\phi = 0$.

Most extended models have generation independent couplings and have generators satisfying Eq. (5), thus predicting that the set of values for $r_{\nu\nu Z}$ versus $r_{\ell\nu W}$ lie on a bounded line segment; this is seen explicitly in Fig. 3. The solid line indicates the range of values permitted in the superstring-inspired effective rank-5 model (ER5M)\(^8\), where the $Z_2$ couplings depend upon a parameter $-90^\circ \leq \theta \leq 90^\circ$. In the figure, $\psi$ labels the point $\theta = 0^\circ$, whereas $\chi$ labels the point $\theta = \pm 90^\circ$ in these models. In the Left-Right Symmetric Model (LRM)\(^9\) the only free parameter is the ratio of the $SU(2)_{L,R}$ couplings, $\kappa = g_R/g_L$\(^10\). Note that on general grounds, it is expected\(^11\) that $\kappa \leq 1$. L labels the point in the figure where $g_R/g_L = 1$, while the extreme case of $\kappa^2 = x_w(1-x_w)^{-1}$ coincides with the point $\chi$. The position of the prediction for the Alternative Left-Right Model (ALRM)\(^12\) is labeled by A, and that of the Foot-Hernandez (FH) Model\(^13\) is labeled by F. The expectations for the $Z_2$ model of Mahanthappa and Mohapatra\(^14\), where the new generator $D$ is proportional to $Y/2$, coincides with those of FH. Although all these models are quite different, their predictions for the ratio $r_{\nu\nu Z}/r_{\ell\nu W}$ are found to lie on a straight line within the bounded region as expected.

Other models shown in Fig 3 demonstrate how Eqs. (10) and (11) can be violated if certain conditions are met. Several models predict that the new generator, $D$, will not satisfy Eq. (5), particularly if the $Z_2$ couplings are proportional to $T_{3L}$. In the Un-unified model of Georgi et al.\(^15\) (labeled by H in the figure),
\[ D \sim t_\chi T^q_{3L} - T^q_{3L} t_\chi^{-1} \]

where \( t_\chi = \tan \chi \) with \( \chi \) being a mixing parameter, and \( T^q_{3L} \) are the third components of the lepton and quark isospin generators. Clearly, Eq. (4) and thus Eqs. (10) and (11) are not satisfied in this case. This can also happen in some compositeness based \( Z_2 \) models or ones which predict that the \( Z_2 \) is just a heavier version of the \( Z_1 \); in the latter case, the prediction is marked by ‘S’ in the figure, while a \( Z_2 \) whose couplings directly depend on \( T^q_{3L} \) will occupy the same position on the figure as in the model of Georgi et al..

A second possible source of deviation from the straight line prediction of Eq. (10) arises from the additional assumption used in Eq. (7) that the leptonic couplings of the \( Z_2 \) are generation independent. In the model of Kuo and collaborators, the third generation couples differently than the first two, whereas, in the Leptophilic model, where differences in lepton number are gauged, the third generation decouples completely from the \( Z_2 \). The expected values of \( r_{\ell\nu W} \) and \( r_{\nu\nu Z} \) in these two models are labeled by K and E, respectively, in Fig. 3. In the Leptophilic case, the values shown in the figure are only for purposes of demonstration, since this \( Z_2 \) cannot be produced at a hadron collider. As a last example, the predictions from the model of Li and Ma, which also results in a violation of universality, are found to lie along the vertical dashed curve with the particular position being dependent upon the value of a model parameter, \( p \). For \( p = 1/3 \), the model of Kuo et al. is recovered. In fact, one finds that the expectations in all models with generation dependent couplings and with \( D \sim T^q_{3L} \) lie along this dashed line, labeled by ‘M’ in Fig. 3. None of these models will generate values of \( r_{\nu\nu Z} \) and \( r_{\ell\nu W} \) which lie on the straight line predicted in Eq. (10).

To summarize our results so far, we have observed that if the following condi-
tions hold:

(i) $s_\phi = 0$

(ii) $[D,T_{iL}] \nu_L, \ell_L > 0$

(iii) $v_{2f}$ and $a_{2f}$ are generation independent,

then and only then will $r_{\nu\nu Z}/r_{\ell\nu W}$ be model independent and both ratios be separately bounded by $1/2 K_{W,Z}$. Thus, if a $Z_2$ is discovered and its corresponding values of $r_{\nu\nu Z}$ and $r_{\ell\nu W}$ are determined, and it is observed that these values lie 'elsewhere' on the $r_{\nu\nu Z} - r_{\ell\nu W}$ plane rather than along the solid line, one can safely conclude that at least one of the above conditions (i)-(iii) are not valid. We have seen, however, that for $s_\phi = 0$ only rather 'exotic' extended models, which do not arise from conventional grand unified theories, fail to satisfy these conditions.

As a final point of this discussion, we stress that a measurement of $r_{\ell\nu W}$ and $r_{\nu\nu Z}$ alone can not uniquely determine the model of origin of the $Z_2$. This can be seen clearly from Fig. 3, e.g., in the case where the LRM and a particular value of $\theta$ from the ER5M predict the same pair of values for $r_{\ell\nu W}$ and $r_{\nu\nu Z}$. Even within the ER5M itself, except for the cases where $r_{\nu\nu Z} = r_{\ell\nu W} = 0$ and $r_{\nu\nu Z} = 1/2 K_Z, r_{\ell\nu W} = 1/2 K_W$ (i.e., the two endpoints of the line), each point along the line corresponds to two distinct values of the $\theta$ parameter resulting from the $v_\ell \leftrightarrow a_\ell$ ambiguity mentioned above. Thus, other data will be required to uniquely determine the origin of the $Z_2$. We note that the leptonic forward-backward asymmetry (in the narrow width approximation) at hadron colliders is also invariant when the vector and axial-vector couplings of the $Z_2$ are flipped for both quarks and leptons. We also mention in passing that, as discussed in Ref. 5, not much information can be gained by considering the ratio $r_{\ell\ell Z}$ ($\equiv r$ in Eq. (6) with $f = \ell$). In this case we
find

\[ r_{\ell\ell Z} = K_Z' \left[ 1 + \left( \frac{2v_{1\ell}a_{1\ell}}{v_{1\ell}^2 + a_{1\ell}^2} \right) \left( \frac{2v_{2\ell}a_{2\ell}}{v_{2\ell}^2 + a_{2\ell}^2} \right) \right] \]

\[ = K_Z' \left[ 1 + 0.135 \left( \frac{2v_{2\ell}a_{2\ell}}{v_{2\ell}^2 + a_{2\ell}^2} \right) \right], \tag{13} \]

where \( K_Z' \) is again a model independent constant and the last equality holds for \( s_\phi = 0 \) and \( x_w = 0.2330 \). The sensitivity to coupling variations in \( r_{\ell\ell Z} \) is thus seen to be substantially reduced compared to both \( r_{\ell\nu W} \) and \( r_{\nu\nu Z} \).

Next we examine what happens when a \( Z_2 \), which satisfies conditions (ii) and (iii) above when \( s_\phi = 0 \), is now allowed to mix with the SM \( Z \), i.e., what happens when \( s_\phi \) is non-zero. Clearly, condition (iii) remains valid, but if (i) is violated so is (ii), as the new generator \( D \) now has a term proportional to \( s_\phi T_{3L} \). For the case of \( r_{\ell\nu W} \), both terms \( H_2 \) and \( H_4 \) in Eq. (4) will now contribute. To be specific, we examine the effect of \( s_\phi \neq 0 \) in the ER5M, ALRM, and LRM (with \( \kappa = 1 \)); all of which satisfy conditions (ii) and (iii) when \( s_\phi = 0 \). We first summarize some properties of the \( Z - Z' \) mixing mechanism before discussing its effect on \( r_{\ell\nu W} \) and \( r_{\nu\nu Z} \).

For an extended model with Higgs scalars transforming only as \( SU(2)_L \) doublets or singlets, the \( Z - Z' \) mass matrix can be written as

\[
\begin{pmatrix}
M_Z^2 & \gamma M_Z^2 \\
\gamma M_Z^2 & M_{Z'}^2
\end{pmatrix},
\tag{14}
\]

with \( \gamma \) being a model dependent parameter of order unity and \( M_Z \) the value of the SM Z-boson mass in the absence of mixing. The eigenvalues of this matrix, \( M_{1,2}^2 \), correspond to the masses of the physical gauge bosons, \( Z_{1,2} \), given in Eq. (3). Since \( M_1 \) is known from LEP\(^{21} \) (= 91.175 GeV), the value of \( \phi \) is calculable from
the above Eq. (14), for a given value of the $Z_2$ mass, $M_2$, in a particular model (which then determines $\gamma$). We can write

$$M_{Z}^{2} = \frac{M_{1}^{2} + M_{2}^{2} - [(M_{2}^{2} - M_{1}^{2})^2 - 4\gamma^2 M_1^2 M_2^2]^{1/2}}{2(1 + \gamma^2)},$$

(15)

$$M_{Z}^{2} = M_{1}^{2} + M_{2}^{2} - M_{Z}^{2},$$

so that one obtains

$$\phi(M_2, \gamma) = \frac{1}{2} \tan^{-1}\left(\frac{2\gamma M_{Z}^{2}}{M_{Z}^{2} - M_{Z}^{2}}\right).$$

(16)

For the various models we consider, $\gamma$ is given by

$$\gamma_{LRM} = -(1 - 2x_w)^{1/2},$$

$$\gamma_{ALRM} = \frac{x_w t_{\beta}^2 - (1 - 2x_w)}{(1 - 2x_w)^{1/2}(1 + t_{\beta}^2)},$$

(17)

$$\gamma_{ER5M} = -2\sqrt{\frac{5x_w}{3}} \left[\left(\frac{c_{\theta}}{\sqrt{6}} - \frac{s_{\theta}}{\sqrt{10}}\right)t_{\beta}^2 - \left(\frac{c_{\theta}}{\sqrt{6}} + \frac{s_{\theta}}{\sqrt{10}}\right)\right](1 + t_{\beta}^2)^{-1},$$

where $t_{\beta} = \tan \beta = v_t/v_b$, the usual ratio of vacuum expectation values (vev’s) responsible for the top and bottom quark masses, and $s_{\theta}(c_{\theta}) = \sin \theta(\cos \theta)$ being the ER5M mixing angle discussed above. Note that if $\theta = -90^\circ$ (model $\chi$) then $\gamma_{\chi} = -(2x_w/3)^{1/2}$ is independent of the value of $\tan \beta$. In obtaining these expressions, we have made the following assumptions: for the ER5M and ALRM which are based on superstring-inspired $E_6$, we assume that the only scalars responsible for $SU(2)_L$ breaking are the SUSY partners of the exotic fermions $N$ and $N^c$ that lie in the 27 representation. Since the quantum numbers of these fields are fixed (for a given value of $\theta$ in the ER5M case), this completely determines $\gamma$ except for
the vev ratio, \( \tan \beta \). In the LRM case, assuming that the left-handed triplet vev is small implies that the fields in the ‘mixed-doublet’ representation, \( 1/2, 1/2 \) of \( SU(2)_L \times SU(2)_R \) are mainly responsible for \( SU(2)_L \) breaking. In this case, the \( \tan \beta \) dependence factors out and one is left with the above expression. We have for the moment also ignored the possible influence of \( W - W' \) mixing in the LRM case.

Since \( \gamma \) is independent of \( \tan \beta \) in both model \( \chi \) and the LRM, the value of \( s_\phi \) is then uniquely determined in these cases once \( M_2 \) is specified. Figures 4a-b display \( r_{\ell \nu W} \) as a function of \( M_2 \) for (a) model \( \chi \) and (b) the LRM with \( \gamma \) as given above (i.e., \( s_\phi \neq 0 \)) and, for comparison, with \( s_\phi = 0 \) set by hand. Clearly the effects of \( s_\phi \neq 0 \) on \( r_{\ell \nu W} \) are quite striking as it produces a very substantial increase in the value of this parameter. (This result was anticipated quite some time ago in Ref. 4.) Since \( \gamma \) is \( \tan \beta \) dependent in the other models, we present \( r_{\ell \nu W} \) as a function of \( \tan \beta \) in Fig. 5a, assuming \( M_2 = 1 \) TeV, for the ALRM and the three ER5M’s corresponding to \( \theta = 0^\circ \) (model \( \psi \)), \( \theta = \sin^{-1} \sqrt{3/8} \simeq 37.76^\circ \) (model \( \eta \)), and \( \theta = -\sin^{-1} \sqrt{5/8} \simeq -52.24^\circ \) (model I). In all cases, varying \( \tan \beta \) away from the point where \( \gamma = 0 \), i.e., \( \tan \beta = 1(2, \simeq 1.5) \) for model \( \psi \) (model \( \eta \), ALRM), which corresponds to \( s_\phi = 0 \), can produce a substantial increase in the value of \( r_{\ell \nu W} \). A minimal value of \( r_{\ell \nu W} \), corresponding to a choice of \( \tan \beta \) which produces \( s_\phi = 0 \), will exist for all values of \( \theta \) in the range \(-\sqrt{5/3} \leq \tan \theta \leq \sqrt{5/3} \).

The value of \( \tan \beta \) which yields these minima is given by

\[
\tan^2 \beta = \frac{1 + \sqrt{3/5} \tan \theta}{1 - \sqrt{3/5} \tan \theta}.
\]  

(18)

Thus, for example, model I, with \( \tan \theta = -\sqrt{5/3} \), will not experience any true minima of \( r_{\ell \nu W} \) for finite values of \( \tan \beta \). This is demonstrated in Fig 5b, which is a
three-dimensional plot of $r_{\ell\nu W}$ as a function of $\tan \beta$ and $\theta$, where a minima "valley" is clearly observable. We conclude that even though $|\phi| \lesssim 10^{-3}$ for $M_2$ in the TeV range, this small amount of mixing can substantially modify the expectations for the value of $r_{\ell\nu W}$ within a given model.

How does $Z - Z'$ mixing modify the values of $r_{\nu\nu Z}$? We anticipate that there is little effect since $s_\phi \neq 0$ does not induce a resonant contribution to this ratio. Hence, for this case, the inclusion of mixing only results in a slight shift of the gauge boson coupling constants. Figures 6a-b show $r_{\nu\nu Z}$ as a function of $M_2$ for (a) model $\chi$ and (b) the LRM, and demonstrate that our expectations are correct. Thus, for models which satisfy conditions (ii) and (iii) of Eq. (12) when $s_\phi = 0$, the cleanest signal for $s_\phi \neq 0$ is that $r_{\ell\nu W}$ would be substantially increased while $r_{\nu\nu Z}$ would suffer only a slight modification. This would correspond to a shift of the model predictions to the right and off of the straight line in Figure 1. If $r_{\nu\nu Z}$ and $r_{\ell\nu W}$ were the only properties of the $Z_2$ that were measured, this would imply that it would be impossible to separate a model which violates conditions (ii) and (iii) with $s_\phi = 0$ from a model which is shifted off of the straight line due to a non-zero value of $s_\phi$. As an example, the Leptophilic model $Z_2$ would be indistinguishable from an ER5M $Z_2$ with $\theta \simeq 10^\circ$ and with a value of $\tan \beta$ which increases $r_{\ell\nu W}$ (via $s_\phi \neq 0$) by a small amount. However, the observation of a violation of the bound on $r_{\nu\nu Z}$ in Eq. (11), would clearly signal that the conditions (ii) or (iii) are violated independently of whether $s_\phi = 0$ or not. Thus, while $r_{\ell\nu W}$ is the more sensitive probe for the validity of condition (i), the ratio $r_{\nu\nu Z}$ does the corresponding job of testing the validity of conditions (ii) and (iii). Combining knowledge of the values of $r_{\ell\nu W}$ and $r_{\nu\nu Z}$ with the measured values of the relative branching fractions for the processes $Z_2 \rightarrow e^+e^-, \mu^+\mu^-$, and $\tau^+\tau^-$ would completely determine the
validity of any of these conditions.

Up to this point, we have ignored the possibility that a new charged gauge boson, $W_2^\pm$, may also participate in 3-body $Z_2$ decays. New charged gauge bosons are present in several of the models discussed above, in particular, the LRM, \textsuperscript{9} ALRM, \textsuperscript{12} Li and Ma model, \textsuperscript{20} and HARV model.\textsuperscript{15} In the Li and Ma and HARV cases, the $Z_2$ and $W_2^\pm$ are essentially degenerate so that $W_2^\pm$ final states in $Z_2$ decay are uninteresting. This is not generally the case for either the LRM or ALRM, where $Z_2 \rightarrow W_2^\pm \ell^+ \nu_R$ is always kinematically accessible. The two body decay $Z_2 \rightarrow W_2^+ W_2^-$ might also be allowed in the LRM for a certain range of the model parameters. To be concrete, we will neglect any effects associated with $W - W'$ mixing (which is naturally absent in the ALRM) and $Z - Z'$ mixing. The $Z_2$ to $W_2^\pm$ mass ratio is

$$\frac{M_{Z_2}^2}{M_{W_2}^2} = \frac{\kappa^2(1 - x_w)}{\kappa^2(1 - x_w) - x_w} \rho_R,$$

where $\kappa \equiv g_R/g_L$ is the ratio of $SU(2)_{L,R}$ couplings, and $\rho_R$ probes the symmetry breaking sector relevant for the heavy gauge boson pair:

$$\rho_R \equiv \frac{2\sum_i T_{3 R_i}^2 v_i^2}{\sum_i [T_{R_i}(T_{R_i} + 1) - T_{3 R_i}^2] v_i^2} = \begin{cases} 1, & \text{Higgs doublets;} \\ 2, & \text{Higgs triplets.} \end{cases}$$

Here, the sum extends over the Higgs sector, $v_i$ is the vev of the $i^{th}$ Higgs boson, and $T_{R_i}(T_{3 R_i})$ is the value of isospin (third component of isospin) of the neutral Higgs boson under $SU(2)_R$.\textsuperscript{10} In the LRM, $0.55 \lesssim \kappa \lesssim 1$ and $\rho_R$ takes either value depending on whether the neutrinos are Majorana or Dirac particles, whereas in the ALRM, $\kappa = \rho_R = 1$ only. The two-body decay $Z_2 \rightarrow W_2^+ W_2^-$ is kinematically accessible in the LRM for the range $\kappa \lesssim 0.63(0.77)$ with a doublet (triplet) $SU(2)_R$
symmetry breaking sector. Figure 7 displays the ratio $M_{Z_2}/M_{W_2}$ as a function of $\kappa$ for both Higgs doublet and triplet representations.

Denoting the $Z_2 W_2^+ W_2^-$ coupling as $\lambda g_R$, we can define a ratio similar to $r_{\ell \nu W}$ above,

$$r_{\ell \nu W_R} \equiv \frac{\Gamma(Z_2 \to W_2^+\ell\nu_R)}{\Gamma(Z_2 \to \ell^{+}\ell^{-})}$$

$$= \frac{G_F M_W^2}{2\sqrt{2\pi}} (v_2^{2} + a_{2}^{2})^{-1} \left\{ \frac{1}{2} [(v_2\ell - a_{2}\ell)^2 + (v_2\nu_R - a_{2}\nu_R)^2] H'_{1} ight. $$

$$+ (v_2\ell - a_{2}\ell)(v_2\nu_R - a_{2}\nu_R) H'_{3}$$

$$\left. + \frac{1}{2} \kappa^2 \lambda^2 H'_{2} ight\} + \kappa \lambda [(v_2\ell - a_{2}\ell) - (v_2\nu_R - a_{2}\nu_R)] H'_{4}$$

(21)

where $H'_{i} = H_{i}$ with the replacements $M_{W} \to M_{W_2}$, $\Gamma_{W} \to \Gamma_{W_2}$. All four terms will contribute to $r_{\ell \nu W_R}$ since the couplings are always linearly proportional to $T_{3R}$ (i.e., the condition $v_{2\ell} - a_{2\ell} = v_{2\nu_R} - a_{2\nu_R}$ doesn’t hold in the LRM or the ALRM). The parameter $\lambda$ introduced above is given by

$$\lambda = \left[ \frac{\kappa^2 - (1 + \kappa^2) x_w}{\kappa^2(1 - x_w)} \right]^{1/2}$$

(22)

which is simply $M_{W_2}/M_{Z_2}$ for $\rho_R = 1$ (in analogy with the factor $c_w = M_{W}/M_{Z}$ which is present in the SM trilinear coupling). We note that the expression for $r_{\ell \nu W_R}$ assumes that $\nu_R$ is light relative to the $Z_2$ and $W_2^{\pm}$; this is an excellent approximation in the LRM with a doublet Higgs representation and in the ALRM where ”$\nu_R$” is expected to be light (the exotic fermion $S_L^\nu$ in the 27 representation...
of $E_6$, Ref. 8, plays the role of the right-handed neutrino in the ALRM). For completeness, we note that the rate for $Z_2$ decay to an on-shell pair of $W_2$’s is given by

$$\Gamma(Z_2 \to W^+_2 W^-_2) = \frac{G_F M^2_{W_2}}{24 \sqrt{2} \pi} M^2_{Z_2} \lambda^2 \kappa^2 \left( \frac{M^2_{Z_2}}{M^2_{W_2}} \right)^2 \left( 1 - \frac{4 M^2_{W_2}}{M^2_{Z_2}} \right)^{3/2} \times \left\{ 1 + 20 \left( \frac{M^2_{W_2}}{M^2_{Z_2}} \right) + 12 \left( \frac{M^2_{W_2}}{M^2_{Z_2}} \right)^2 \right\} . \quad (23)$$

This width is potentially quite large for smaller values of $\kappa$, as in this case $M^2_{Z_2} \gg M^2_{W_2}$ and no mixing angle suppression appears. Figure 8 presents the reduced width $\Gamma_R \equiv \Gamma(Z_2 \to W^+_2 W^-_2)/M_{Z_2}$ as a function of $\kappa$ for both types of symmetry breaking sectors; note that in order to set the scale and guide the eye, the corresponding ratio for the SM $Z$ decay into $e^+e^-$ is $\simeq 9.1 \times 10^{-4}$. We see from the figure that $\Gamma_R$ is only significant for the doublet Higgs representation when $\kappa \lesssim 0.61$, but remains much larger in the triplet case out to values of $\kappa \simeq 0.73$.

Figure 9 shows the ratio $r_{\ell\nu W_R}$ as a function of $\kappa$ for both the triplet and doublet symmetry breaking schemes assuming $M_{Z_2} = 4$ TeV for purposes of demonstration. (This choice of $M_{Z_2}$ was made in order to avoid too light a value of $M_{W_2}$ for small $\kappa$.) In the Higgs triplet case, $r_{\ell\nu W_R}$ remains above $10^{-2}$ for almost all the entire range of $\kappa$, whereas, the ratio drops below this value for $\kappa \simeq 0.63$ in the case of scalar doublets. The very large value of $r_{\ell\nu W_R}$ at small $\kappa$ values arises from the strong resonant contribution, $Z_2 \to W^+_2 W^-_2$, in a manner similar to what we saw above in the case of $Z-Z'$ mixing for $Z_2 \to W^+_1 W^-_1$. Similar results are obtainable for other values of $M_{Z_2}$. For the ALRM, where $\kappa = \rho_R = 1$, $r_{\ell\nu W_R}$ is found to be extremely small and unobservable, i.e., $\lesssim 10^{-4}$.  

16
As mentioned above, one could also gain information from the decays, $Z_2 \rightarrow W^+ + \text{jets}$ and $Z_2 \rightarrow Z^+ + \text{jets}$, however these particular processes will suffer from more severe SM backgrounds, such as $W$ or $Z + n - \text{jet}$ production. Not only are the leptonic processes, $Z_2 \rightarrow W\ell\nu$ and $Z_2 \rightarrow Z\nu\bar{\nu}$, cleaner to begin with, but their kinematic distributions should be able to differentiate them from SM backgrounds such as $pp \rightarrow ZZ, WW$, as well. The fermions in the decay $Z_2 \rightarrow f\bar{f}$ will come out relatively back to back and the gauge boson, which is bremsstrahlunged off of one of the fermion legs, will be approximately collinear with the fermion and relatively soft. The resonance graph, $Z_2 \rightarrow W^+W^-$ will have different kinematical properties. Detailed background studies are clearly needed, but are beyond the scope of this work.

In summary, we have examined the 3-body decays, $Z_2 \rightarrow W\ell\nu$ and $Z_2 \rightarrow Z\nu\bar{\nu}$ and have found that they can be used to obtain much information on the properties of the $Z_2$ for $M_2 \lesssim 2 - 3$ TeV. Besides being used to differentiate between possible extended gauge models, these processes can measure the amount of $Z - Z'$ mixing, the generation dependence of the $Z_2$ couplings, and the properties of the new generator associated with the $Z_2$. In particular, if the $Z_2$ arises from a more "conventional" grand unified theory and $Z - Z'$ mixing is absent, the predictions for the 3-body decays lie on a straight line in the $r_{\ell\nu W} - r_{\nu\nu Z}$ plane, with the slope of the line being determined by the mass of the $Z_2$. If any of the conditions stated in Eq. (12) are violated, then the values of these decay rates will not lie on this line. The effect of $Z - Z'$ mixing is to increase the rate for $r_{\ell\nu W}$, while keeping the prediction for $r_{\nu\nu Z}$ relatively unchanged. Hence, a measurement of $r_{\nu\nu Z} > \frac{1}{2}K_Z$ is a definite signal for the violation of conditions (ii) and (iii) of Eq. (12), while a measurement of $r_{\ell\nu W} > \frac{1}{2}K_W$ could also be a signature for non-zero $Z - Z'$.
mixing. We also find that the decays into a new heavy charged gauge boson, 
$Z_2 \rightarrow W_2^\pm \ell \bar{\nu}$, can occur in some models at observable rates and would yield even more information on the origin of the extended gauge sector.

We urge our experimental colleagues to consider these promising 3-body decays!

FIGURE CAPTIONS

1) Feynman diagrams responsible for the decay $Z_2 \rightarrow \ell \nu W$.

2) Number of events expected for the process $Z_2 \rightarrow \ell \nu W$ neglecting $Z - Z'$ mixing at the SSC with $10^4$ pb$^{-1}$ of integrated luminosity as a function of the $Z_2$ mass. From top to bottom, the dashed-dotted curve corresponds to the SSM, the dashed curve to the HARV model (with $s_\phi = 0.5$), the dotted curve to the ALRM, the solid curve to the ER5M $\chi$, and the short-dotted curve to the LRM.

3) Values of $r_{\nu\nuZ}$ and $r_{\ell\nu W}$ predicted by the various models discussed in the text when $s_\phi = 0$.

4) A comparison of the predicted values of the ratio $r_{\ell\nu W}$ in (a) model $\chi$ and (b) the LRM as a function of $M_2$ both with (solid curve) and without (dashed curve) $Z - Z'$ mixing.

5) (a) $r_{\ell\nu W}$ as a function of $\tan \beta$ assuming $M_2 = 1$ TeV for the $E_6$ ER5M I (corresponding to $\theta = -52.24^\circ$), represented by the solid curve; model $\eta$ ($\theta = 37.76^\circ$), dotted curve, and model $\psi$ ($\theta = 0^\circ$), dashed curve; as well as the ALRM, dash-dotted curve. (b) Three-dimensional figure of $r_{\ell\nu W}$ as a function of $\tan \beta$ and $\theta$ in the ER5M. The x-axis corresponds to $\theta$ (ranging from $-100^\circ$ to $+100^\circ$), the y-axis to $\tan \beta$ (ranging from $10^{-1}$ to $10^1$), and the z-axis to $r_{\ell\nu W}$ (ranging from 0 to 5).

6) Same as Fig. 4 but for the ratio $r_{\nu\nuZ}$.

7) The ratio $M_{Z_2}/M_{W_2}$ as a function of $\kappa$ for a triplet (solid curve) or doublet (dashed-dot curve) symmetry breaking sector.

8) The reduced width, $\Gamma_R$, for the same cases displayed in Fig. 7.
9) The ratio $r_{\ell\nu W_R}$ for the same Higgs representations as shown in Fig. 7.
