Abstract

We propose a scenario in which the Planck scale is dynamically linked to the electroweak scale induced by top condensation. The standard model field content, without the Higgs, is promoted to a 5D warped background. There is also an additional 5D fermion with the quantum numbers of the right-handed top. Localization of the zero-modes leads, at low energies, to a Nambu-Jona-Lasinio model that also stabilizes the radion field dynamically thus explaining the hierarchy between the Planck scale and $v_{EW} = 174$ GeV. The top mass arises dynamically from the electroweak breaking condensate. The other standard model fermion masses arise naturally from higher-dimension operators, and the fermion mass hierarchies and flavor structure can be explained from the localization of the zero-modes in the extra dimension. If any other contributions to the radion potential except those directly related with electroweak symmetry breaking are engineered to be suppressed, the KK scale is predicted to be about two orders of magnitude above the electroweak scale rendering the model easily consistent with electroweak precision data. The model predicts a heavy (composite) Higgs with a mass of about 500 GeV and standard-model-like properties, and a vector-like quark with non-negligible mixing with the top quark and mass in the 1.6–2.9 TeV range. Both can be within the reach of the LHC. It also predicts a radion with a mass of a few GeV that is very weakly coupled to standard model matter.
1 Introduction

In the past couple of decades there has been a tremendous effort, both theoretical and experimental, to try to understand the electroweak scale. An important driving force has come from the desire to understand how this scale is related, if at all, to other scales in nature such as the Planck scale. Dynamical symmetry breaking through strong interactions provides a beautiful conceptual framework for understanding naturally hierarchically different scales. The analogy with the QCD interactions played a prominent role in the application of the idea to the generation of the electroweak (EW) scale itself, when the Technicolor model was introduced in the late 1970’s [1, 2]. Fermion masses were later introduced via extended technicolor (ETC) [3, 4] (for recent developments see [5]). Because of the difficulty in generating a large top quark mass in the ETC theory, a more natural proposal where top quark condensation breaks the electroweak symmetry was first proposed in [6, 7, 8], and later developed in [9, 10, 11]. Fitting the observed top quark mass was finally possible in the context of the top seesaw model [12] (see [13] for a comprehensive study). More recently, extra-dimensional scenarios [14, 15, 16, 17] have led to a simple realization of the basic ingredients of Topcolor models [18]. For a review of strong dynamical electroweak symmetry breaking and an extended list of references, see [19].

In this paper we assume that the standard model (SM) fields propagate in a 5D warped background [20], resulting in strong interactions that lead to a simple picture where the EW symmetry is broken by a fermion-anti fermion condensate. The source of the strong interactions responsible for the condensate is related to the 5D SU(3)C QCD interactions, specifically to the gluon KK modes, which can easily be sufficiently strong to trigger the condensation. Our main observation is that the resulting vacuum energy in the presence of the condensate depends on the separation between the “ultraviolet” (UV) and “infrared” (IR) branes, L. This is because the KK gluon masses and the couplings of the condensing fermions to the KK gluons are L-dependent so that the vacuum energy in the presence of condensation is also L-dependent. Thus, a potential for the radion field is induced. Crucially, the (electroweak induced) vacuum energy has a minimum that naturally leads to an inter-brane distance parametrically larger than the 5D curvature scale. As a result, the Planck, the Kaluza-Klein (KK) and the electroweak scales are all related dynamically. It is widely appreciated that a complete solution to the hierarchy problem within warped scenarios [21] requires a specification of a radion stabilization mechanism. Notice that, unlike the well-known Goldberger-Wise mechanism for radion stabilization [22], we do not add by hand dynamics for the sole purpose of stabilizing the ra-
dion field. In this sense, our mechanism is closer in spirit to the proposal of radion stabilization through Casimir energies [23]. We go beyond the previous proposals in that the stabilization of the distance between the branes is directly related to electroweak symmetry breaking (EWSB), and leads to a rather non-trivial link between various scales in the theory (however, see [24]).

We illustrate the radion stabilization mechanism in a simple toy model in Section 2. The mechanism can be studied within an effective Nambu-Jona-Lasinio (NJL) model [25] in the large $N$ limit. We show, in particular, that the EW induced potential has a well-defined minimum. Based on this potential, the Planck/EW scale hierarchy is obtained provided a certain coupling is about 10% above a critical value. The size $L$ is adjusted dynamically and one finds that, when the Planck/EW scale ratio is reproduced, the KK scale is predicted to be a factor of about 200 above the EW scale. Thus, the radion stabilization mechanism we propose not only explains the large hierarchy between the Planck and EW scales, but also the little hierarchy between the KK and EW scales. Furthermore, the relaxation of the radion field to the minimum of the potential energy ensures that typically only one of the fermions condenses, the one closest to the IR brane. In the context of the SM, the top quark is the most natural candidate to condense. We also discuss other, Casimir-like contributions to the radion potential that need to be suppressed for the little hierarchy above to survive. Such suppression may be obtained in the presence of additional fermionic degrees of freedom.

In Section 3 we propose a simple model that accommodates the fermion masses, including the top quark mass: the $SU(3)_C \times SU(2)_L \times U(1)_Y$ gauge fields and the SM fermion field content are supplemented by an additional quark field with the quantum numbers of the right-handed (RH) top quark, and are assumed to propagate in the bulk of a warped 5D space. There is no fundamental scalar field. We choose boundary conditions such that at energies below the KK scale, there is one vector-like fermion $\chi$, in addition to the SM fermions. We assume that the SM fermion closest to the IR brane is one of the $SU(2)_L$ quark doublets (which is then identified as the left-handed (LH) third generation quark doublet). Its condensation partner is a linear combination of the RH top quark and $\chi_R$, which is the most general and natural case allowed by the underlying 5D structure. Therefore, the EW symmetry is effectively broken by top condensation [11], and the fact that the top mass is of order the EW scale (and much larger than the other fermion masses) is a natural consequence. The fact that the condensate involves a linear combination of RH fields leads to a version of the top seesaw [12] that easily accommodates the observed top mass. In this sense, the model we propose can be regarded as a UV completion for the top condensation scenario, that also leads to a novel realization of the
top seesaw scheme.

In Section 3 we also show how the EW scale and the top mass are obtained in the above model. We also present in some detail how the light fermion masses can arise from higher-dimension operators involving the top and $\chi$ fields. Radion stabilization determines that the KK scale is of order several tens of TeV. The low-energy spectrum includes, besides the SM fermions and gauge bosons, a (composite) Higgs with a mass of about 500 GeV and a vector-like quark that mixes with the top quark. In Section 4 we show that the EW constraints imply that the vector-like quark mass should be in the 1.6–2.9 TeV range. We also show that the radion field has a mass of a few GeV and a “decay constant” of order a few hundred TeV, which makes its detection challenging. The collider phenomenology of the present scenario is also briefly discussed. Section 5 contains our conclusions.

Finally, we provide two appendices with technical discussions. In Appendix A we clarify how the strong coupling relevant to the physics of condensation is related to the strong coupling physics intrinsic to the 5D theory. We also estimate carefully the size of 4-fermion interactions that are expected to be present in the 5D theory, and that give rise, in the present scenario, to the masses of the SM fermions other than the top. We collect in Appendix B several formulas that are relevant for the EW precision analysis.

2 Condensates and Radion Stabilization

We start by considering the simplest toy model that displays the main features of the radion stabilization mechanism. This will allow us to understand the main idea in a simple setting. A fully realistic implementation is considered in Section 3.

2.1 $SU(N_c)$ with Two Flavors

Consider an $SU(N_c)$ gauge theory (to be identified later with the color group) in the AdS$_5$ background

$$ds^2 = e^{-2ky}g_{\mu\nu}dx^\mu dx^\nu - dy^2,$$

where $\mu$ runs over the 4D noncompact directions and $0 \leq y \leq L$. We also consider two bulk fermions, $\Psi_1$ and $\Psi_2$, in the fundamental representation of $SU(N_c)$. Their boundary conditions are chosen so that one gives rise to a LH zero-mode, $\psi_{1L}$, while the other gives rise to a RH zero-mode, $\psi_{2R}$. Here we are mainly interested in the physics of these fermion zero-modes.
which have profiles given by
\[ f_c(y) = \sqrt{\rho_c} e^{(\frac{1}{2} - c)ky}, \]  
where
\[ \rho_c \equiv \frac{(1 - 2c)kL}{e^{(1-2c)kL} - 1} \]
is the normalization factor, and \( c \) stands for \( c_1 \) or \( c_2 \), which parametrize the fermion 5D mass terms in units of the curvature scale \( k \). Our conventions are such that, independently of chirality, the zero-modes are localized near the UV (IR) brane for \( c > 1/2 \) (\( c < 1/2 \)). Tree-level exchange of the first-level gauge KK mode leads to 4-fermion operators of the form
\[ -\frac{g_{c_1} g_{c_2}}{M_{KK}^2}(\bar{\psi}_{1L} T^A \gamma^\mu \psi_{1L})(\bar{\psi}_{2R} T^A \gamma^\mu \psi_{2R}) = \frac{g_{c_1} g_{c_2}}{M_{KK}^2}(\bar{\psi}_{1L} \psi_{2R})(\bar{\psi}_{2R} \psi_{1L}) + \mathcal{O}(1/N_c), \]
where \( T^A \) are the \( SU(N_c) \) generators, the parenthesis indicates how the color contractions are performed, and the right-hand side is obtained by Fierz rearrangement. Also, \( M_{KK} \) is the lightest KK gluon mass and \( g_c \) is its coupling to a fermion with localization parameter \( c \), given by the overlap integral
\[ g_c = \frac{g_5}{L^{3/2}} \int_0^L dy |f_c(y)|^2 |f_G^{(1)}(y)|, \]
where \( g_5 \) is the 5D gauge coupling, and \( f_G^{(1)}(y) \) is the first-level KK gluon wavefunction. Other operators that involve only LH or only RH fermions will play no role in the following discussion (notice they have the “wrong” sign to spontaneously break the Lorentz symmetry, as discussed in [26]). Also, in the 5D effective theory there are local 4-fermion interactions (suppressed by the cutoff of the 5D theory, \( \Lambda \)). We argue in Appendix A that the effects due to these four-fermion interactions are expected to be subdominant compared to those obtained by integrating out the gauge KK modes.

The 4-fermion interaction due to gauge boson exchange, Eq. (1), is always attractive (i.e. \( g_{c_1} g_{c_2} > 0 \)) and, if sufficiently strong, can lead to a fermion-antifermion condensate and a low-energy scalar degree of freedom, as reviewed below. It is important to notice that one can also consider the 4-fermion interactions induced by integrating the second and higher gauge KK modes out. However, it is easy to check that the relevant couplings, analogous to Eq. (5),

1We define all wavefunctions so that the normalization reads \( (1/L) \int_0^L dy |f(y)|^2 = 1 \), without warp factors.
are significantly smaller than the one associated with the first-level gauge KK mode. This can be understood from the oscillating behavior of the heavier gauge KK mode wavefunctions, which generally leads to cancellations. One can also consider the 4-fermion interactions among the fermion KK modes that arise when heavier KK gauge bosons are integrated out. But again, the associated couplings are significantly smaller than Eq. (5). As will be explained in Subsection 2.4, the largest coupling [which corresponds to Eq. (5)] is only slightly above the critical value for the condensation to happen. As a result we do not expect fermion condensation in any of the above “KK channels”. This should be contrasted to the situation in flat space, where all non-vanishing couplings among KK modes are equal, and condensation happens in all channels that exist below the cutoff of the 5D theory [15].

Therefore, we concentrate on the 4-fermion operators that involve the lightest fermions and arise from exchange of the lightest gauge KK mode. Their physical effects can be studied in the 4D effective theory valid below the KK scale, and can be analyzed as in the NJL model in a large \( N \) approximation [25]. Since our main interest is in how this well-known condensation mechanism can also stabilize the radion and how the compactification and condensation scales are related, we start by establishing the dependence of the relevant parameters on \( L \).

### 2.2 \( L \)-dependence of Microscopic Parameters

Both the coupling \( g_c \) and the KK scale \( M_{KK} \) depend on the size of the extra dimension \( L \). In order to find an analytical expression for this dependence, we resort to the following trick: it is easy to obtain an analytical expression for the coefficient of the 4-fermion operator, Eq. (4), induced by integrating out the full tower of gluon KK modes, using propagator techniques [27]. On the other hand, these effects are saturated to a very good approximation by the lightest KK gluon, which is the one that concerns us. This observation allows us to obtain an approximate expression for \( g_c \) in Eq. (5). The effects of the complete KK tower sum up to

\[
\sum_{n=1}^{\infty} \frac{g_n^2}{M_n^2} = \frac{g_0^2 k}{k^2 e^{-2kL}} \left[ f_1(c_1, c_2) - \frac{f_2(c_1, c_2)}{kL} + \frac{1}{4k^2 L^2} \right],
\]

where

\[
f_1(c_1, c_2) = f_2(c_1, c_2) = \frac{1}{2} \left( c_1 \ln \frac{c_1 + c_2}{c_1 - c_2} + c_2 \ln \frac{c_1 + c_2}{c_1 - c_2} \right).
\]

Ref. [16] considered a warped space analog. However, no fermion bulk masses were considered and, since for \( c = 0 \) the fermion KK wavefunctions reduce to sines and cosines, a situation similar to flat space ensues. For arbitrary \( c \)-parameters, however, the condensation occurs only among the lightest fermions (zero-modes, or ultra-light modes, as described in Section 3), due to exchange of the first-level gauge KK modes.
where $g_n$ is the coupling to the fermion zero-modes of the $n$-th KK gluon with mass $M_n$. When $c_{1,2} < 1/2$ (i.e. fermions localized near the IR brane), one has

$$f_1(c_1, c_2) = \frac{(1 - 2c_1)(1 - 2c_2)(3 - c_1 - c_2)}{2(3 - 2c_1)(3 - 2c_2)(2 - c_1 - c_2)}, \quad (7)$$

$$f_2(c_1, c_2) = \frac{45 - 28[c_1(3 - c_1) + c_2(3 - c_2)] + 16c_1c_2(3 - c_1)(3 - c_2)}{2(3 - 2c_1)^2(3 - 2c_2)^2}, \quad (8)$$

where exponentially small effects have been neglected.

The lightest KK gluon mass is given by

$$M_{\text{KK}} = x_1 k e^{-kL}, \quad (9)$$

where $x_1 \approx 2.45$ has a very mild dependence on $L$ that, for simplicity, we ignore for the moment.

Using the fact that Eq. (6) is almost saturated by this lightest mode, and comparing to Eq. (4), we find

$$g_{c_1}g_{c_2} \approx g_5^2 k x_1^2 \left[ f_1(c_1, c_2) - \frac{f_2(c_1, c_2)}{kL} + \frac{1}{4k^2 L^2} \right]. \quad (10)$$

Indeed, it is easy to check numerically that $g_{c_1}g_{c_2}$ computed from Eqs. (5) or (10) agree rather well for the parameters of interest.

We also point out that the functions $f_1(c_1, c_2)$ and $f_2(c_1, c_2)$ are positive definite, a fact that will be used below. This can be checked explicitly when $c_{1,2} < 1/2$ and Eqs. (7) and (8) apply. When $c_i > 1/2$, these two functions become exponentially small.

### 2.3 Radion Potential

The 4-dimensional effective theory can lead to a potential for the radion through the $L$-dependence of $M_{\text{KK}}$ and $g_{c_1}g_{c_2}$, as given in the previous subsection. As we will see, such a potential is intimately connected to the formation of a condensate $\langle \overline{\psi}_{1L}\psi_{2R} \rangle$ in a NJL model with the 4-fermion interactions given in Eq. (4). If the coupling in Eq. (10) is sufficiently large, a nontrivial condensate forms and gives rise to a scalar fermion-antifermion bound state. The simplest way to study this phenomenon is by rewriting the 4D theory including the 4-fermion interactions of Eq. (4), in terms of an auxiliary “Higgs” field, $H$, as

$$\mathcal{L}_4 = i\overline{\psi}_{1L} \not{D}\psi_{1L} + i\overline{\psi}_{2R} \not{D}\psi_{2R} - M_{\text{KK}}^2 H^\dagger H + (g_5 H \overline{\psi}_{1L}\psi_{2R} + \text{h.c.}) \quad (11)$$
where $D$ is the gauge covariant derivative with respect to the zero-mode gluon, and we have omitted the gluon kinetic term for simplicity. By integrating out the auxiliary field $H$ the original Lagrangian is recovered, with the identification $g^2 = g_0 g_c > 0$. We should regard the Lagrangian (11) as holding at the scale $M_{KK}$. Renormalization group running to lower scales leads to

$$L_4(\mu) = Z_L \bar{\psi}_1 L \partial_\mu \psi_1 + Z_R \bar{\psi}_2 R \partial_\mu \psi_2 + (Z_g \bar{\psi}_1 \psi_1 \bar{H} \psi_2 + \text{h.c.})$$

$$+ Z_H \partial_\mu H \partial_\mu H - m_H^2 H^\dagger H - \frac{\lambda}{2} (H^\dagger H)^2,$$

which shows that a scalar kinetic term is induced, and $H$ can be thought as a dynamical degree of freedom below the scale $M_{KK}$. Furthermore, the Higgs squared mass parameter, that starts out positive at the $M_{KK}$ scale, can be driven to negative values through radiative effects. If we ignore the effects of the Higgs self-interactions, which enter at subleading order in the $1/N_c$ expansion, the running arises from fermion loops. Cutting off the loop integrals at $M_{KK}$ leads to

$$m_H^2 \approx M_{KK}^2 \left[ 1 - \frac{g_0^2 N_c}{8 \pi^2} \left( 1 - \frac{\mu^2}{M_{KK}^2} \right) \right], \quad \lambda \approx \frac{g_0^4 N_c}{8 \pi^2} \ln \left( \frac{M_{KK}^2}{\mu^2} \right),$$

which indicates that $H$ acquires a non-vanishing vacuum expectation value (VEV) provided

$$g_0^2 > G_c^2 \equiv \frac{8 \pi^2}{N_c}.$$  

As discussed above, the parameters that determine this VEV depend on the size of the extra dimension so that we effectively obtain a scalar potential for $\langle H \rangle$ and $L$, that should be minimized simultaneously. We rewrite this potential as

$$V(H, L) = m_H^2(L) H^\dagger H + \frac{\lambda(L)}{2} (H^\dagger H)^2$$

$$= \frac{\bar{\lambda}(L)}{2} \left[ H^\dagger H + \frac{m_H^2(L)}{\lambda(L)} \right]^2 - \frac{m_H^2(L)}{2 \lambda(L)},$$

where, as a result of 5D general covariance, the radion dependence enters only through the (renormalized) parameters

$$m_H^2 = \frac{m_H^2}{Z_H}, \quad \bar{\lambda} = \frac{\lambda}{Z_H^2},$$

Parameters associated with the gauge and fermion sectors also depend on $L$, but do not contribute to the radion potential as long as these fields do not acquire VEV’s, which we assume to be the case.
where
\[
Z_H = \frac{N_c g_0^2}{16 \pi^2} \ln \left( \frac{M_{\text{KK}}^2}{\mu^2} \right) .
\]  

(17)

We see that a radion potential is induced only when the condition (14) is fulfilled so that \( \langle H^\dagger H \rangle = -\bar{m}_H^2/\bar{\lambda} \). Referring to Eq. (10) and given that the function \( f_1(c_1, c_2) \) is positive definite, as mentioned above, we conclude that the condensate can form provided
\[
g_5^2 k x_1^2 f_1(c_1, c_2) > G_c^2 ,
\]  

(18)

which will occur whenever the fermions are sufficiently localized towards the IR brane. The reason is simply that the last two terms in Eq. (10) vanish as \( kL \to \infty \), and therefore there is always a region in \( L \) where \( g_{c_1} g_{c_2} > G_c^2 \).\footnote{Since \( f_2(c_1, c_2) > 0 \), the opposite inequality, \( g_5^2 k x_1^2 f_1(c_1, c_2) < G_c^2 \), can lead to a condensate only for \( kL \ll 1 \), when the third term in Eq. (15) can dominate. We do not consider such a possibility here.} Assuming that the inequality (18) is satisfied, and noting that \( f_2(c_1, c_2) \) is also positive definite, we see that there is a critical value, \( L_c \), defined by
\[
g_5^2 k x_1^2 \left[ f_1(c_1, c_2) - \frac{f_2(c_1, c_2)}{kL_c} + \frac{1}{4k^2L_c^2} \right] = G_c^2 ,
\]  

(19)

such that for \( L > L_c \) the condensate forms. It is then clear from the form of \( V(H, L) \) that when \( L > L_c \) and imposing \( \partial V/\partial H = 0 \) [i.e. \( \langle H^\dagger H \rangle = -\bar{m}_H^2/\bar{\lambda} \)], \( \partial V/\partial L \) receives contributions only from the second term in Eq. (15). Thus, the radion potential is simply given by
\[
V_{\text{eff}}(L) = -\frac{\bar{m}_H^4}{2\bar{\lambda}} \theta(L - L_c) 
\begin{equation}
\approx -\frac{M_{\text{KK}}^4}{4\pi^2} \left( \frac{1}{g_{c_1}^2} - \frac{1}{g_{c_2}^2} \right)^2 \theta(L - L_c) ,
\end{equation}

(20)

where \( \theta(x) \) is the Heaviside step function, equal to 1 for \( x \geq 0 \) and zero otherwise. The renormalization scale \( \mu \) should be taken of the order of the Higgs condensate: \( \mu \sim v_{\text{EW}} < M_{\text{KK}} \). In Eq. (20) we neglected the term \( \mu^2/M_{\text{KK}}^2 \) in \( m_H^2 \) [see Eq. (15)] since it is a negligible effect when there is a hierarchy between \( v_{\text{EW}} \) and \( M_{\text{KK}} \) (which will be argued below). We observe that \( V_{\text{eff}}(L) \) is negative and vanishes both for \( L < L_c \) and for \( L \to \infty \) (for small \( L \) there is no condensate, hence no radion potential, while for large \( L \), \( M_{\text{KK}} \) goes to zero exponentially). Therefore, the potential (20) has a minimum for some \( L > L_c \) and stabilizes the radion whenever the condition (18) is satisfied. The radion potential is shown in Fig. 1.
Let us emphasize the properties of the radion potential induced by the condensate that lead to a minimum: these are the vanishing of the potential at small $L$ due to the 4-fermion interaction turning subcritical, and the vanishing at $L \to \infty$ (a consequence of the fact that in the uncompactified limit, 5D general covariance forbids non-derivative terms that involve the radion field). We comment on possible additional contributions to the radion potential, as well as on strong coupling uncertainties, in Subsection 2.6 below. It is, however, interesting to understand the striking properties of the radion potential Eq. (20) and the resulting physical picture when it is the dominant effect. This will allow us to abstract the essential properties and see that it is not implausible that the resulting picture can arise even when other effects are taken into account.

### 2.4 Scales: Leading Order Analysis

In this subsection we explore the connection between the dynamically determined size of the extra dimension and the Higgs condensate:

$$\langle H \rangle \equiv v_{\text{EW}} = \sqrt{\frac{m_H^2}{\lambda}} = \frac{M_{\text{KK}}}{\sqrt{2}} \sqrt{\frac{1}{G_c^2} - \frac{1}{g_\psi^2}}. \quad (21)$$

Here we neglected, as before, the effects of the Higgs self-interactions. It is useful to define the functions

$$\bar{f}_i = g_5^2 k x_1^2 f_i(c_1, c_2), \quad \text{for } i = 1, 2, \quad (22)$$
Figure 2: Left panel: $kL_{\text{min}}$ as a function of $\bar{f}_1/G^2_c$ [see Eqs. (22) and (23)]. The variation in $\bar{f}_1$ is obtained by varying $c_1 = c_2$ for fixed “underlying” KK gluon coupling $g_5\sqrt{k} = 5.08$. Right panel: Ratio of the KK scale to the Higgs VEV as a function of $kL_{\text{min}}$. The red dots indicate the point where the Higgs VEV is at the electroweak scale, $v_{\text{EW}}$. The choice of $g^2_5k$ is such that at this point we reproduce the “observed” $\alpha_s(\mu = M_{\text{KK}}) \approx 0.068$, where $M_{\text{KK}} \approx 35$ TeV.

where the $f_i(c_1, c_2)$ are given at tree-level by Eqs. (7) and (8). In terms of these, the condition that ensures that a condensate exists, Eq. (18), is simply $\bar{f}_1 > G^2_c$. Since, as we will see, the radion is stabilized at values $kL \gg 1$, we will neglect the third term in Eq. (10) in order to simplify the following analytical expression. One can easily include the full expression in the numerical studies.

The minimum of the radion potential, Eq. (15), is then given by

$$
k_{L_{\text{min}}} = \frac{\bar{f}_2}{f_1 - G^2_c} + \sqrt{1 + \frac{2\bar{f}_1}{G^2_c f_2} (\bar{f}_1 - G^2_c) - 1} \approx \frac{\bar{f}_2}{f_1 - G^2_c} + \frac{1}{2},$$

(23)

where the second equality holds when $\bar{f}_1/G^2_c - 1 \ll 1$. In this case we get $kL_{\text{min}} \gg 1$. To get a more quantitative idea, we note that $\bar{f}_2/\bar{f}_1$ lies between 2 and 3 for $-1 < c_1 = c_2 < 0$. Thus, if $\bar{f}_1$ is within 10% of $G^2_c$ one gets $kL_{\text{min}}$ of order $20 - 30$, roughly what is required to explain the Planck-weak scale hierarchy.

Note also that once $kL_{\text{min}}$ is determined by the above dynamical mechanism, the low-energy
gauge coupling is computed from
\[
\alpha_s = \frac{g_s^2}{4\pi L_{\text{min}}}.
\] (24)

If we are aiming at explaining the Planck-weak scale hierarchy, so that \(k L_{\text{min}} \sim 33 - 34\), and identify \(\alpha_s\) with the strong coupling constant, we see that the “fundamental” KK gluon coupling is determined to be \(\sqrt{g_s^2 k} \sim 6\), although its precise value depends on the actual matching scale \(M_{\text{KK}}\), both through the value of \(k L_{\text{min}}\) and the RG running of \(\alpha_s\) up to the KK scale.

In the left panel of Fig. 2 we show \(k L_{\text{min}}\) as a function of \(\bar{f}_1/G_c^2\). We obtain different values of \(\bar{f}_1\) by varying the localization of the fermions. For illustration purposes, we took \(c_1 = c_2\), but the situation is similar in the more general case. We fix \(g_s^2 k\) so that \(\alpha_s\) has the correct value at \(M_{\text{KK}}\) when the condensate has the correct value, \(\langle H \rangle = v_{\text{EW}} = 174\) GeV. These two requirements uniquely fix \(g_s^2 k\) and \(\bar{f}_1\) (for \(c_1 = c_2\) and \(k = 2 \times 10^{17}\) GeV we find \(c_1 = -0.62\)). The size of the extra-dimension, \(k L\), is fixed by the minimization of the potential to be \(k L_{\text{min}} \approx 30\).

The hierarchy between the weak and Planck scales is explained when \(\bar{f}_1\) is within 10% of \(G_c^2\), a relatively moderate tuning. The KK scale is then predicted to be 35 TeV (see right panel of Fig. 2). Interestingly, the radion is stabilized at a point where the actual coupling of the KK gluon to fermions, \(g_{\psi}^2 = g_{c_1} g_{c_2}\) [see Eq. (10)], is rather close to the critical coupling \(G_c^2\). Specifically, we get
\[
g_{\psi}^2 \approx G_c^2 + \frac{(\bar{f}_1 - G_c^2)^2}{2\bar{f}_2}, \tag{25}
\]
which gives \(g_{\psi}^2/G_c^2 - 1 \approx 10^{-3}\). Notice that \(g_{\psi}^2\) is closer to \(G_c^2\) than the original 10% input by a factor \((g_{\psi}^2/G_c^2)/(\bar{f}_1 - G_c^2) \approx (\bar{f}_1 - G_c^2)/(2\bar{f}_2) = \mathcal{O}(1/\bar{f}_2)\), which is small because \(\bar{f}_2 \sim g_s^2 k x_1^2 \gg 1\), a consequence of the underlying strong dynamics. This accounts for the factor of about 1/100 of additional suppression in the difference \(g_{\psi}^2 - G_c^2\). As a result, a relatively large hierarchy between \(v_{\text{EW}}\) and \(M_{\text{KK}}\) is predicted:
\[
v_{\text{EW}} \approx M_{\text{KK}} \left(\frac{\bar{f}_1 - G_c^2}{2G_c^2}\right) \sqrt{\frac{1}{\bar{f}_2}}, \tag{26}
\]

---

5We use the RG equation with the SM field content plus one additional \(SU(2)_L\) singlet quark with a mass of \(a \sim 2\) TeV, for reasons discussed in Section 3 to obtain the value of \(\alpha_s(M_{\text{KK}})\) from \(\alpha_s(M_Z)\).

6Defining the sensitivity by \(S = \partial \log v_{\text{EW}}/\partial \log \bar{f}_1\) [28], we obtain \(S \approx (f_2/\bar{f}_1)/\bar{f}_1(G_c^2 - 1)^{-2}\). As argued in [29], the fine-tuning should be obtained by comparison with the typical sensitivity, defined as an appropriate average, which in our case is \(S = 12\bar{f}_2 G_c^2/[(\bar{f}_1 - G_c^2)^2(3\bar{f}_{\text{max}} + G_c^2)]\). For \(|c_1|, |c_2| \leq 1\), \(\bar{f}_{\text{max}} \approx 1.35 G_c^2\), and we find \(S/S \approx 10\), which corresponds to a 10% fine-tuning.
as shown on the right panel of Fig. 2. In that figure we also marked the point where \( \langle H \rangle = v_{\text{EW}} \), which is associated with a KK scale \( M_{\text{KK}} \approx 35 \text{ TeV} \) (and \( k L_{\text{min}} \approx 30.27 \)). We stress that the hierarchy between \( M_{\text{KK}} \) and \( v_{\text{EW}} \) of about 200 requires only a moderate 10% tuning, so that there is essentially no little hierarchy problem. This is a consequence of the radion stabilization mechanism that relaxes \( L \) to a point where \( g_\psi^2 \) is driven very close to the critical value. This also implies that generically only the fermions closest to the IR brane, which have the strongest couplings to the first-level KK gluon, will condense. Other fermions which are somewhat further away from the IR brane will have subcritical couplings. This is also true for the fermion KK modes, which have couplings to the KK gluons that are smaller than those of the lightest fermion modes (see comments in the last paragraph of Subsection 2.1).

2.5 Scales: Improved Analysis

To estimate more precisely the renormalized fermion Yukawa coupling \( \bar{g}_\psi \) and the Higgs quartic coupling \( \bar{\lambda} \), hence the Higgs boson mass, at a low energy scale \( \mu \), we include the SM gauge couplings and Higgs self-interactions into the renormalization group (RG) equations for \( \bar{g}_\psi \) and \( \bar{\lambda} \). At one loop order these are

\[
16\pi^2 \frac{d \bar{g}_\psi}{d \ln \mu} = \bar{g}_\psi \left[ \frac{9}{2} \bar{g}_\psi^2 - 8 \bar{g}_3^2 - \frac{9}{4} \bar{g}_2^2 - \frac{17}{12} \bar{g}_Y^2 \right],
\]

\[
16\pi^2 \frac{d \bar{\lambda}}{d \ln \mu} = 12 \left[ \bar{\lambda}^2 + (\bar{g}_\psi^2 - \frac{1}{4} \bar{g}_Y^2 - \frac{3}{4} \bar{g}_2^2) \bar{\lambda} + \frac{1}{16} \bar{g}_Y^4 + \frac{1}{8} \bar{g}_Y^2 \bar{g}_2^2 + \frac{3}{16} \bar{g}_2^4 - \bar{g}_\psi^4 \right],
\]

while the SM gauge couplings satisfy

\[
16\pi^2 \frac{d \bar{g}_i}{d \ln \mu} = b_i \bar{g}_i^3,
\]

with

\[
b_3 = -7 + \frac{2}{3} n_f, \quad b_2 = -\frac{19}{6} + \frac{1}{6} n_s, \quad b_1 = \frac{41}{6} + \frac{1}{6} n_s + \frac{8}{27} n_f.
\]

Here we introduced \( n_s \) and \( n_f \) to take into account additional particles beyond the standard model, which will be discussed in a realistic model in Section 3. We will choose \( n_s = 1 \) for

\footnote{The Higgs mass parameter also receives quadratically divergent contributions from gauge boson loops, which should be added to Eq. (13). Since these couplings are perturbative, this shift changes the value of the critical coupling \( G_2^2 \) (defined by the vanishing of the Higgs mass parameter) only slightly. As mentioned before, the loop contribution due to the Higgs self-interactions is also small in the large \( N_c \) limit. The details of the minimization of the radion potential are expected to change only slightly as a result of these effects.}
Figure 3: Left panel: the fermion mass $m_{\psi}$ as a function of the running scale $\mu$. Right panel: the Higgs boson mass $m_h$ as a function of $\mu$. The solid (blue) line is for the boundary condition $\bar{g}_\psi(M_{KK}) = \infty$, while the dotted (orange) line is for the boundary condition $\bar{g}_\psi(M_{KK}) = \sqrt{4\pi}$. The intersection with the dashed (red) line, $m(\mu) = \mu$, determines the particle masses: $m_{\psi} = 375 \pm 25$ GeV and $m_h = 475 \pm 25$ GeV.

$\mu > 10$ TeV and $n_s = 0$ for $\mu \leq 10$ TeV, while $n_f = 1$ for $\mu > 2$ TeV and $n_f = 0$ for $\mu \leq 2$ TeV. This corresponds to having one additional Higgs doublet at 10 TeV and one additional top quark-like fermion at 2 TeV. To solve the RG equations, we use the “compositeness conditions” $\bar{g}_\psi = \infty$ and $\bar{\lambda} = \infty$ at the $M_{KK}$ scale [11], which corresponds to having vanishing Higgs kinetic term and quartic coupling at the compositeness scale, $M_{KK} \approx 35$ TeV. In the following numerical studies the SM gauge couplings at $M_Z$ are taken from the PDG [30], while their experimental errors are neglected since they are expected to be small compared to the theoretical uncertainties.

In Fig. 3, we show the fermion and the Higgs boson masses as functions of the energy scale $\mu$, that follow from integration of Eqs. (27) and (28). We use the mass-shell condition $m(\mu = m_{phys}) = m_{phys}$ to define the physical mass. To estimate the error in our perturbative calculation of a strongly coupled theory, we report two boundary conditions for $\bar{g}_\psi$. One is $\bar{g}_\psi(M_{KK}) = \infty$ as shown in the solid (blue) line, while the other is $\bar{g}_\psi(M_{KK}) = \sqrt{4\pi}$ as shown in the dotted (orange) line. In this way, we find a fermion mass of $m_{\psi} = 375 \pm 25$ GeV, while the Higgs boson mass is $m_h = 475 \pm 25$ GeV. The actual masses of the new fermion and the new Higgs doublet are not important for the numerical solutions of the RG equations. If we neglect the effects from the new particle’s contributions by choosing $n_s = n_f = 0$ for all scales in Eq. (29), the final values for $m_{\psi}$ and $m_h$ are only changed by around 1 GeV, and hence
contribute negligibly to the errors of $m_\psi$ and $m_h$. However, the RG improved masses of the new fermion and Higgs doublet are relevant to study the phenomenological consequences of this scenario.

2.6 Corrections to the Condensate-Induced Radion Potential

We studied in the previous subsections the physical consequences of having the interbrane separation $L$ dynamically fixed through a potential arising as a result of fermion-anti fermion condensation. Whether the condensate forms or not depends on $L$, thus leading to a non-trivial connection between the condensation scale (which we call $v_{\text{EW}}$) and the KK scale $M_{\text{KK}} = x_1 \tilde{k}$, with $\tilde{k} \equiv k e^{-kL}$ and $x_1 \approx 2.5$. Interestingly, a dynamically induced little hierarchy between $M_{\text{KK}}$ and $v_{\text{EW}}$ arises (see Subsection 2.4). The relevant quantities that enter in this argument are $\bar{f}_1$ and $\bar{f}_2$, which we can think of as parametrizing the strength of the 4-fermion interactions in a large $kL$ expansion, according to $g_\psi^2 = \bar{f}_1 - \bar{f}_2/kL + \mathcal{O}(1/kL)^2$. This strength should be compared to a critical value $G_c^2$, above which the fermion condensation occurs. In a large $N_c$ approximation, $G_c^2$ is given by $8\pi^2/N_c$. For finite $N_c$ one might expect that there is still a critical value, although it may differ from the large $N_c$ result by order one. Determining the precise $G_c^2$ at finite $N_c$ would require a fully non-perturbative analysis. Absent this, we take the attitude that the large $N_c$ result may be a useful guide even for $N_c = 3$. Notice that in this case, $G_c^2 \sim 8\pi^2/N_c \approx 26$, a value that is in the ballpark of $\log M_P/v_{\text{EW}}$, and is at the heart of the mechanism we have presented. The effects of fermion localization give a freedom that accounts for the fact that these two quantities are not numerically identical. The important point is that the precise value of $G_c^2$ was not essential in our analysis (as long as it is not too far from the large $N_c$ result).

Besides the large $N_c$ approximation, that gives some analytic control to explore our stabilization mechanism, we also used in the quantitative analysis of the previous subsections the tree-level results for the functions $\bar{f}_1$ and $\bar{f}_2$, as given in Eqs. (7) and (8). Given that the matching at the KK scale between the 4D effective theory and the 5D model involves strongly coupled physics, one can expect that the non-perturbative functions $\bar{f}_1$ and $\bar{f}_2$ can differ by order one from the tree-level values, even in the large $N_c$ approximation. Notice that the analysis of the relation between scales given in Subsection 2.4 is phrased in terms of $\bar{f}_1$, $\bar{f}_2$ and

---

8We argue in Appendix A that this strong coupling should not be interpreted as a signal of the breakdown of the 5D description. The 5D description breaks down at a scale $\Lambda$ somewhat larger than $M_{\text{KK}}$.

9We thank K. Agashe for discussions on this point.
$G_2^2$. In particular, we only use that $\bar{f}_1, \bar{f}_2 \sim G_2^2$ where the large values arise from $\bar{f}_{1,2} \sim g_2^2 k x_1^2$, thus reflecting the strength of the coupling between fermion zero-modes and the KK gluon. It is also important that $\bar{f}_1$ and $\bar{f}_2$ be positive, which is indeed the case at tree-level.

The lesson is that provided the fully non-perturbative values of $\bar{f}_1$ and $\bar{f}_2$ are of the same order and have the same sign as the tree-level result, the qualitative picture discussed above applies (notice that the sign of $\bar{f}_1$ corresponds to the statement that the 4-fermion channel is attractive). Again, absent a fully non-perturbative analysis, we cannot assess whether this assumption is indeed fulfilled, but we find it extremely interesting that a little hierarchy can be dynamically induced under this seemingly mild assumption. In particular, one might expect the hierarchy between $M_{KK}$ and $v_{EW}$ to be of order $G_3^3 c$ [setting $\bar{f}_1 - G_2^2 c = 2 - 3$ in Eq. (26), roughly a 10% tuning of microscopic parameters]. In order to get a more quantitative estimate of the non-perturbative effects on the radion stabilization, one can test how much $M_{KK}$ changes (keeping $v_{EW}$ and $\alpha_s(M_Z)$ fixed) if $\bar{f}_{1,2}$ change by a factor of order one compared to the tree-level values (our intention is only to roughly mimic possible $O(1)$ non-perturbative effects, and we do not change here the $c_1$ and $c_2$ dependence given by $\bar{f}_{1,2}^{\text{tree}}$). For instance, if $\bar{f}_2 = 2\bar{f}_2^{\text{tree}}$ one finds $M_{KK} \sim 25$ TeV, while for $\bar{f}_2 = \bar{f}_2^{\text{tree}}/2$ one finds $M_{KK} \sim 50$ TeV [there is slightly less sensitivity to corrections to $\bar{f}_1$: as it varies from $\bar{f}_1^{\text{tree}}/2$ to $2\bar{f}_1^{\text{tree}}$, $M_{KK}$ varies from $\sim 30$ TeV to $\sim 40$ TeV]. We infer that a KK scale of a few tens of TeV may be expected, as already suggested by the tree-level matching. We also note that the above examples require the same 10% tuning of microscopic parameters that was found in Subsection 2.4. It is important to recall that given the values of $\bar{f}_1$ and $\bar{f}_2$, the radion potential has the striking property that the ratio of $M_{KK}$ to $v_{EW}$ is quite insensitive to the only mass scale in the Lagrangian, namely $k$ (as we will show later, only the radion mass and couplings are sensitive to this high scale).

Also to be addressed are the effects of other contributions to the radion potential, not associated with the condensation. For instance, we neglected above the $L$-dependence of $x_1$ in Eq. (9). This dependence contributes to the calculable Casimir energy contribution [31, 32] and should be taken into account. It was shown in Ref. [32] that the contribution from localized fermions is exponentially smaller than the contribution due to gauge fields (or other fields with approximately flat zero-modes). The latter takes the form $V_{\text{Casimir}} = [k^4/(16\pi^2)] [g_s \beta_1/(kL)]$, where $g_s = 2 \times 12 + 2$ is the number of degrees of freedom of the gauge fields in the SM plus the graviton contribution, and $\beta_1$ is a calculable function that depends on the localized kinetic terms. For $kL \approx 30$ and $M_{KK} \approx 200 v_{EW} \approx 35$ TeV, one has $V_{\text{Casimir}} \approx 10^4 \times g_s \beta_1 v_{EW}^4$. This should be compared to the value of the potential Eq. (20) at its minimum, which using Eq. (21)
can be written as \[ \frac{16\pi^2}{3\log(M_{KK}^2/v_{EW}^2)} \] \[ v_{EW}^4 \approx 5v_{EW}^4. \] Thus, it appears that a suppression \( \beta_1 \sim 10^{-5} \) is required, or else the dynamically induced little hierarchy would be questionable. In fact, for gauge fields with negligible brane kinetic terms one has \( \beta_1 \approx -1 \) (i.e. the branes are attracted to each other), and the minimum of \( V_{\text{eff}}(L) \) in Eq. (20) is destabilized. However, \( \beta_1 \) depends on the brane kinetic terms and can easily be positive, in which case the radion potential has a minimum and the connection to EWSB is maintained (the physics of brane-localized kinetic terms in regards to Casimir energies was first pointed out for the flat case in [23]). For instance, an IR localized kinetic term with a coefficient \( kr_{IR} \approx 0.5 \) (\( kr_{IR} \approx 2 \)) leads to \( \beta_1 \approx 0.1 \) (\( \beta_1 \approx 1 \)). Minimizing \( V(L) = V_{\text{eff}}(L) + V_{\text{Casimir}}(L) \), and requiring that \( v_{EW} \) and \( \alpha_s \) have the observed values, as in the previous sections, one finds that \( M_{KK} \approx 5 \) TeV (\( M_{KK} \approx 3 \) TeV). The above remarks also show that there is a value of the brane kinetic term that makes the one-loop Casimir energy vanish. In particular, \( kr_{IR} \approx 0.440 \) leads to \( \beta_1 \sim 10^{-5} \). In fact, even for \( \beta_1 \sim 10^{-4} \) –where the Casimir contribution at the “unperturbed” minimum is somewhat larger than the condensate potential– a minimization of the potential including both the Casimir and the condensation contributions leads to \( M_{KK} \sim 25 \) TeV. The non-trivial minimum arises from the condensation, and the link between \( M_{KK} \) and \( v_{EW} \), as well as the little hierarchy, survive.

We also mention a second way to suppress the Casimir contribution. The important observation is that the leading order Casimir effect \[ \propto \frac{\tilde{k}^4}{16\pi^2kL} \], at one-loop order, depends only on the particle content. Also, the contribution can be positive or negative depending on the statistics (as well as on the b.c.’s). We can therefore simply add a number of “inert” 5D fermions with \( c = 1/2 \) that match the degrees of freedom of the SM gauge fields. Writing a small IR localized Majorana mass so as to avoid an additional fermionic zero-mode, the Casimir effects due to the gauge fields and the additional fermions cancel at leading order, and the remnant is of order \[ g_s\delta\beta_1/16\pi^2\delta^2 m_0^2 \approx 50g_s v_{EW}^2 m_0^2 \], where \( m_0 \) is the mass of the lightest fermion state in the KK tower. \[ \delta \beta_1 \approx 1.26 \] is a calculable numerical factor, and we used \( M_{KK} \approx 200v_{EW} \) on the r.h.s. For \( g_s = 26 \), this is comparable to the potential from condensation for \( m_0 \sim 10 \) GeV, and becomes rapidly negligible for smaller \( m_0 \) (note that any choice for \( m_0 \) is technically natural). We are taking advantage here of the fact that the one-loop Casimir energy is independent of the interactions of the particles involved and is sensitive only to the spectrum. This is no longer true at two-loop order. Since for such light fermions one needs

\[ ^{10}\text{We thank H. Davoudiasl for discussions on this scenario.} \]

\[ ^{11}\text{In the case of the } W^\pm \text{ and } Z, \text{ } m_0 \text{ is the mass splitting between the fermion and the gauge bosons.} \]
their couplings to the SM to be sufficiently small that they have escaped detection (they could even be completely “inert”\textsuperscript{12}, there is no cancellation between the fermions and gauge boson contributions to the Casimir energy at two loops. We expect the size of the net effect to be of order \(N_c g_s^2 k^4/(16\pi^2)^2\) for some calculable \(\tilde{\beta}_1\), where \(g_s\) is the QCD coupling. We have checked that for \(g_s \approx 1\), \(g_s = 2 \times 8\) and \(\tilde{\beta}_1 \lesssim 1/2\) there is a minimum of the combined Casimir and condensation potential, with \(M_{KK} \gtrsim 10\) TeV. It is quite possible that this mild suppression of \(\tilde{\beta}_1\) can be easily achieved without fine-tuning, either as a result of small factors arising in the detailed two-loop computation, or due to the presence of IR brane-localized kinetic terms, as suggested by the one-loop result.

Finally, there are non-calculable contributions to the radion potential that, through the brane tensions, are sensitive to the UV completion of the 5D theory. Up to a constant, radion-independent term (that depends on the UV brane tension, \(T_{UV}\), and should be adjusted to have vanishing 4D cosmological constant), the total radion potential takes the form

\[
V(L) = \frac{B k^4 e^{-4kL}}{16\pi^2} + V_{\text{Casimir}}(L) + V_{\text{eff}}(L),
\]

where the non-calculable contribution is parametrized by a free parameter \(B\), \(V_{\text{Casimir}}(L)\) is the calculable Casimir contribution discussed above, and \(V_{\text{eff}}(L)\) is the contribution from fermion condensation, Eq. \((31)\). Ref. \[32\] showed that a minimum with \(kL \sim 30\) can arise from the first two terms in Eq. \((31)\), provided one has \(B \sim O(1)\) (this can be achieved by adjusting the renormalized IR brane tension). In this case it would still be possible to generate a non-trivial condensate if the fermion zero-modes are sufficiently localized towards the IR brane, but the close connection between radion stabilization and the condensate (to be identified with the EWSB scale) would be lost. If, on the other hand, \(B\) is more suppressed, a minimum can instead arise from the last two terms in Eq. \((31)\). Note that assuming a suppressed \(B\) would correspond to imposing \(T_{IR} \approx -24M_{KK}^3 k\). This latter relation is similar to the one required in the original Randall-Sundrum proposal \[21\]. However, a suppressed \(B\) within the present setup

\textsuperscript{12}If, on the other hand, the new fermions interact with matter like gauginos, there are cancellations that make the two-loop Casimir contribution negligible compared to the potential from the condensate. In this case, the (long-lived) “gluinos” would have to be sufficiently heavy to have escaped detection, probably 100–200 GeV \[33, 34\]. The one-loop Casimir contribution discussed above is then larger than the radion potential from condensation, but it does not necessarily wipe out the minimum, nor the connection between \(M_{KK}\) and \(v_{EW}\).

\textsuperscript{13}There can also be other, subdominant contributions, for instance associated with the QCD phase transition, that we neglect.

\textsuperscript{14}The Casimir contribution is not essential for the existence of the minimum, and could also be suppressed, as discussed above.
would not only stabilize the distance between the two branes, but also establish a connection with the condensate. In this work we have assumed that the non-calculable part is sufficiently suppressed, for instance by a careful choice of the IR brane tension, and hence a little hierarchy between $M_{KK}$ and $v_{EW}$ is induced.

As a last technical remark, we note that since the potential at the minimum is of order the EW scale and much smaller than $\bar{k}$, we expect the gravitational backreaction on the warped background to be small.

3 The Planck and EW Scales from a Top Seesaw

Having discussed the mechanism for condensation and radion stabilization in Section 2, we now turn our attention to a realistic implementation where the above condensation mechanism is responsible for EW symmetry breaking and the generation of all SM fermion masses. The fermions that condense must then carry $SU(2)_L \times U(1)_Y$ quantum numbers. One possibility is to consider a fourth generation as done recently in Ref. [17]. This leads to a Higgs mass of order a TeV, and a fourth generation fermion with a mass in the several hundred GeV range. The light fermion masses can be generated from local 4-fermion operators suppressed by the cutoff scale $\Lambda$ [see Eq. (53) below], as discussed in Subsection 3.3 below. However, such effects are naturally suppressed, and can hardly be expected to generate the top quark mass (see Subsection 3.3 and Appendix A). We therefore consider a scenario where the top quark takes an active role in the condensation mechanism. The EW scale is then closely connected to top condensation [11]. As we will see, our setup leads naturally to a Top Seesaw [12] structure, so that a top quark parametrically lighter than the Higgs can be easily accommodated.

3.1 The Model

In more detail, the SM model is embedded into 5D fields propagating on the background of Eq. (1) as follows. We concentrate on the “top sector”, which arises from an $SU(2)_L$ doublet 5D fermion, $\Psi_{QL}$, with hypercharge 1/3, plus two $SU(2)_L$ singlet 5D fermions, $\Psi_1$ and $\Psi_2$, with hypercharge 4/3. This setup has exactly one additional $SU(2)_L$ singlet compared to the standard minimal construction. The boundary conditions are chosen so that $\Psi_{QL}$ has

$^{15}$ In spite of the notation, these fields should not be identified with the fields of the toy model of Subsection 2.1.

$^{16}$ There is no corresponding enlargement of the field content in the first two generations. In summary, we simply take the 5D SM field content without the Higgs field and add a single 5D fermion with the quantum numbers of the RH top quark. A Chern-Simons term to cancel anomalies resulting from the compactification
a LH zero-mode, $Q_L = (t_L, b_L)$. Since $\Psi_1$ and $\Psi_2$ have the same quantum numbers, we can write a general two by two 5D Dirac mass matrix for them. Such a mass matrix can always be diagonalized, but the boundary conditions in the basis where the 5D mass matrix is diagonal need not be of the simple $(-, +)$ or $(+, +)$ type for the two individual fields. Rather, one should allow for general linear combinations of the fields with the same quantum numbers to be assigned Neumann or Dirichlet boundary conditions. From now on, we will define $\Psi_1$ and $\Psi_2$ as Dirac mass eigenstates with Dirac masses written as $c_1 k$ and $c_2 k$ respectively, while the Dirac mass associated with the doublet is written as $c_Q k$. The boundary conditions for the $SU(2)_L$ singlets are described in more detail below.

We choose one linear combination of $\Psi_1$ and $\Psi_2$ to have a RH zero-mode, while the orthogonal linear combination has an ultralight Dirac KK mode. The low-energy (i.e. below the KK scale) singlet fermions are denoted by $t_R, \chi_L$ and $\chi_R$. In general, $t_R$ lives in both RH 5D fermions, $\Psi_{1R}$ and $\Psi_{2R}$, as does the ultralight Dirac KK mode, $\chi$. The KK decomposition in the RH sector reads

$$\Psi_{1R}(x, y) = \frac{e^{\frac{3}{2}ky}}{\sqrt{L}} [h_1(y) t_R(x) + k_1(y) \chi_R(x) + \cdots] ,$$

$$\Psi_{2R}(x, y) = \frac{e^{\frac{3}{2}ky}}{\sqrt{L}} [h_2(y) t_R(x) + k_2(y) \chi_R(x) + \cdots] ,$$

where $\cdots$ represent higher KK modes, and $h_i(y), k_i(y)$ are the wavefunction profiles for $t_R$ and $\chi_R$, respectively. The “misalignment” between the boundary conditions and the general Dirac mass matrix for $\Psi_1$ and $\Psi_2$ is parametrized by an angle $\theta$. We require $\cos \theta \Psi_{1R} + \sin \theta \Psi_{2R}$ to obey $(+, +)$ boundary conditions, so that it contains the zero-mode $t_R$, while the orthogonal combination $-\sin \theta \Psi_{1R} + \cos \theta \Psi_{2R}$ is assigned $(-, +)$ boundary conditions and contains the ultralight mode $\chi_R$.

For the zero-mode $t_R$, the wavefunction profiles are

$$h_1(y) = \frac{\cos \theta}{\sqrt{a(c_1, c_2)}} e^{(\frac{1}{2} - c_1)ky} , \quad h_2(y) = \frac{\sin \theta}{\sqrt{a(c_1, c_2)}} e^{(\frac{1}{2} - c_2)ky} .$$

Here $a(c_1, c_2)$ is a dimensionless parameter that normalizes the 4D fermion wavefunction according to $\frac{1}{L} \int_0^L dy (|h_1(y)|^2 + |h_2(y)|^2) = 1$, and is given by

$$a(c_1, c_2) = \frac{\cos^2 \theta}{\rho_{c_1}} + \frac{\sin^2 \theta}{\rho_{c_2}} ,$$

needs to be added, but it has no impact on the physics we are interested in.
where $\rho_c$ was defined in Eq. (3) [\(\rho_{c_1} \text{ and } \rho_{c_2} \text{ are precisely the normalization factors of the zero-modes of 5D Dirac fermions obeying } (+, +) \text{ boundary conditions}. For } c_1, c_2 < -1/2, \text{ the solutions for the wavefunction profiles of the ultralight KK mode, } \chi_R, \text{ are approximately}

\[ k_1(y) \approx -\tan \theta \sqrt{\frac{\rho_{c_1}}{\rho_{c_2}}} h_1(y), \quad k_2(y) \approx \cot \theta \sqrt{\frac{\rho_{c_2}}{\rho_{c_1}}} h_2(y), \quad \text{(35)} \]

where the approximation is very good even for $y$'s far from the IR brane. Again the wavefunction of $\chi_R$ is properly normalized here. The ultralight Dirac mass, that marries the $\chi_L$ and $\chi_R$ fields, is

\[ m_d \approx \sqrt{\frac{(1 + 2c_1)(1 + 2c_2)[(2c_2 - 1)e^{(1+2c_2)kL} + (2c_1 - 1)\tan^2 \theta e^{(1+2c_1)kL}]}{1 + 2c_1 + (1 + 2c_2)\tan^2 \theta}} k \ e^{-kL}. \quad \text{(36)} \]

This formula is valid for $c_2 < -1/2$ and when $c_1$ and $c_2$ are not too close to each other. It shows the Dirac mass to be exponentially smaller than $\tilde{k} \equiv k \ e^{-kL}$. For $\theta = 0$, the ultralight mode arises purely from $\Psi_{2R}$, and has a mass $m_d \approx \sqrt{4c_2^2 - 1} e^{(\frac{1}{2}+c_2)kL} \tilde{k}$.

The couplings of the lightest KK gluon to the RH 4D fermions can be read from the 5D fermion covariant kinetic terms after replacing them by their KK decomposition, Eq. (32), as well as the gluon one. Noticing that $h_i(y)$ and $k_i(y)$ are proportional to the same exponential function, these couplings take the form

\[ \left( \frac{g_{c_1}}{\rho_{c_1} \rho_{c_2} a(c_1, c_2)} (\tilde{t}_R \quad \tilde{\chi}_R) \left( -\sqrt{\frac{\rho_{c_2}}{\rho_{c_1} \rho_{c_2}}} \sin \theta \cos \theta \quad -\sqrt{\frac{\rho_{c_1} \rho_{c_2}}{\rho_{c_1}^2}} \sin \theta \cos \theta \right) G_{\mu}^A T^A \gamma^\mu \left( \frac{t_R}{\chi_R} \right) \right) \]

\[ + \left( \frac{g_{c_2}}{\rho_{c_1} \rho_{c_2} a(c_1, c_2)} (\tilde{t}_R \quad \tilde{\chi}_R) \left( \sqrt{\frac{\rho_{c_1} \rho_{c_2}}{\rho_{c_1}^2}} \sin \theta \cos \theta \quad \sqrt{\frac{\rho_{c_1} \rho_{c_2}}{\rho_{c_2}^2}} \sin \theta \cos \theta \right) G_{\mu}^A T^A \gamma^\mu \left( \frac{t_R}{\chi_R} \right) \right). \quad \text{(37)} \]

where $g_{c_i}$ is defined exactly as in Eq. (5) (i.e. as the coupling of the first KK gluon to a generic fermion with (+, +) b.c.’s and localization parameter $c_i$). The above two matrices can be diagonalized by the same rotation matrix. Changing the RH chiral fermions basis to a new basis $t'_R \equiv \cos \alpha t_R + \sin \alpha \chi_R$ and $\chi'_R \equiv -\sin \alpha t_R + \cos \alpha \chi_R$, so that the fermion couplings to the first KK gluon are diagonal, we have the simple result

\[ (\tilde{t}'_R \quad \tilde{\chi}'_R) \left( \begin{array}{cc} g_{c_1} & 0 \\ 0 & g_{c_2} \end{array} \right) G_{\mu}^A T^A \gamma^\mu \left( \frac{t'_R}{\chi'_R} \right), \quad \text{(38)} \]

with the mixing angle

\[ \alpha = -\tan^{-1} \left( \sqrt{\frac{\rho_{c_1}}{\rho_{c_2}}} \tan \theta \right). \quad \text{(39)} \]
Effectively, $t'_R$ and $\chi'_R$ behave like RH zero-modes of two non-mixing Dirac fermions with localization parameters $c_1$ and $c_2$. They couple to the LH light fermion $\chi_L$ with 4D Dirac masses, $\sin \alpha m_d$ and $\cos \alpha m_d$, respectively, where $m_d$ is given in Eq. (36). We notice, for future reference, that the normalization factor in Eq. (34) can be variously expressed as

$$a(c_1, c_2) = \frac{\cos^2 \theta \sec^2 \alpha}{\rho_{c_1}} = \frac{\sin^2 \theta \csc^2 \alpha}{\rho_{c_2}} = \frac{\sec^2 \alpha}{\rho_{c_1} + \tan^2 \alpha \rho_{c_2}},$$

so that the wavefunction profiles of Eqs. (33) and (35) can be simply written in terms of the fundamental zero-mode wavefunctions of Eq. (2) as

$$h_1(y) = \cos \alpha f_{c_1}(y), \quad h_2(y) = \sin \alpha f_{c_2}(y),$$
$$k_1(y) \approx \sin \alpha f_{c_1}(y), \quad k_2(y) \approx -\cos \alpha f_{c_2}(y).$$

The wavefunction of $\chi_L$ is obtained from $\chi_R$ using the equation of motion. Decomposing the 5D left-handed field as

$$\Psi_{1L}(x, y) = \frac{e^{\frac{3}{2}ky}}{\sqrt{L}} l_1(y) \chi_L(x) + \cdots, \quad \Psi_{2L}(x, y) = \frac{e^{\frac{3}{2}ky}}{\sqrt{L}} l_2(y) \chi_L(x) + \cdots,$$

and considering the region $c_{1,2} < -1/2$, we have

$$l_1(y) \approx -\frac{\sin \theta}{\sqrt{a(-c_2, -c_1)}} e^{(\frac{1}{2}+c_1)ky}, \quad l_2(y) = \frac{\cos \theta}{\sqrt{a(-c_2, -c_1)}} e^{(\frac{1}{2}+c_2)ky},$$

where the normalization factors were defined in Eq. (34). The coupling of $\chi_L$ to the first KK gluon, which we call $g_{\chi_L}$, can be calculated simply by substituting the wave function profiles $l_1(y)$ and $l_2(y)$ into Eq. (5) and summing them together. As one can see, for the parameter range of interest, $c_{1,2} < -1/2$, the LH part of the Dirac fermion is localized close to the UV brane. As a consequence, $g_{\chi_L}$ is suppressed compared to $g_{c_1}$ and $g_{c_2}$. More importantly, it has the opposite sign to $g_{c_1}$ and $g_{c_2}$, a fact that will be relevant in the following.

### 3.2 EWSB, Radion Stabilization and the Top Mass

It is now simple to study the low-energy theory that describes the light fermions, $Q_L = (t_L, b_L)$, $t'_R$, $\chi_L$ and $\chi'_R$. The most important effects due to the heavy physics are the 4-fermion interactions that are induced by integrating out the KK gluons at tree-level. These lead to the breaking of the EW symmetry and the stabilization of the radion along the lines discussed...
in Section 2. The top mass can also be easily accommodated via a top seesaw. After Fierz rearrangement, the 4-fermion operators are

\[
\frac{1}{M_{KK}^2} \left[ g_{\chi LXR}^2 \langle \overline{\chi}_L \chi_R \rangle (\overline{\chi}_R \chi_L) + g_{\chi LT}^2 \langle \overline{\chi}_L t'_R \rangle (\overline{\chi}_R t_L) \\
+ g_{QXR}^2 \langle \overline{Q}_L \chi'_R \rangle (\overline{\chi}'_R Q_L) + g_{Qt}^2 \langle \overline{Q}_L t'_R \rangle (\overline{t}_R Q_L) \right],
\]

(44)

where \( M_{KK} \) is the KK gluon mass, and \( g_{\chi LXR}^2 = g_{\chi L} g_{c_2}, \ g_{\chi LT}^2 = g_{\chi L} g_{c_1}, \ g_{QXR}^2 = g_{c_2} g_{c_2}, \ g_{Qt}^2 = g_{c_2} g_{c_1} \). The analytical dependence of these coupling on \( L \) can be obtained from Eq. (10), with

\[
g_5^2 \rightarrow g_{s,5}^2 + \left( \frac{Y_i}{2} \right) \left( \frac{Y_i}{2} \right) g_{Y,5}^2.
\]

Here \( g_{s,5}^2 \) and \( g_{Y,5}^2 \) are the \( SU(3)_C \) and \( U(1)_Y \) 5D gauge couplings, respectively, and the \( Y_i \)'s are the appropriate hypercharges, with \( Y_\chi = Y_{tR} = 4/3 \) and \( Y_Q = 1/3 \). There is no contribution from the \( SU(2)_L \) interactions since all terms in Eq. (44) involve the \( SU(2)_L \) singlets \( t'_R \) or \( \chi'_R \). For \( g_{QXR}^2 \) and \( g_{Qt}^2 \), Eqs. (7) and (8) can be used, since they apply for fermions localized near the IR brane. However, as mentioned at the end of the previous subsection, one finds that \( g_{\chi L} \) has the opposite sign to \( g_{c_1} \) and \( g_{c_2} \), so that \( g_{\chi LXR}^2 \) and \( g_{\chi LT}^2 \) are negative. Thus, KK gluon exchange in these channels is repulsive, and no singlet bound states can form. Bound states and condensation can only occur for \( \overline{Q}_L \chi'_R \) and \( \overline{Q}_L t'_R \).

In order to analyze the physics of EW symmetry breaking, we introduce two scalar \( SU(2)_L \) doublets, \( H_1 \) and \( H_2 \), with hypercharge \( Y_H = -1 \). In terms of these auxiliary scalar fields, the last two terms in Eq. (44) are rewritten as

\[
L_4 \supset g_{QXR} \overline{Q}_L H_1 \chi'_R + g_{Qt} \overline{Q}_L H_2 t'_R - M_{KK}^2 (H_1^\dagger H_1 + H_2^\dagger H_2),
\]

(46)

which is understood to hold at the KK scale, \( M_{KK} \). We do not write the four fermion operators involving \( \chi_L \) since they do not lead to scalar bound states, nor condensation. At lower scales the scalar fields \( H_1 \) and \( H_2 \) become dynamical and, depending on the strength of their interactions with the fermions, their squared masses can become negative, thus triggering the condensation. The induced scalar kinetic terms, quartic couplings and mass renormalizations can be obtained by RG evolution. The RG equations receive contributions from the Yukawa couplings exhibited

\footnote{For a fermion zero-mode with localization parameter \( c_{1UV} > 1/2 \) (localized near the UV brane) interacting via KK gluon exchange with a second fermion with \( c_{1IR} < 1/2 \) (localized near the IR brane), one has, for \( kL \gg 1 \), \( g_{cUV} g_{cIR} \approx -g_5^2 k x_1^2 [f_2(c_{1IR})/(kL) + 1/(4k^2 L^2)] \) with \( f_2(c_{1IR}) = (5 - 12c_{1IR} + c_{1IR}^2)/(4(3 - 2c_{1IR})^2) > 0. \)
in Eq. (46), as well as from the gauge interactions and the induced quartic self-interactions. At lower energies, the Lagrangian, with kinetic terms understood, takes the form

\[
\mathcal{L}_4 \supset \bar{g}_{Q\chi R} Q_L \chi_R' + \bar{g}_{Qt} Q_L H_2 t_R' - \bar{m}_{H_1}^0 H_1^\dagger H_1 - \bar{m}_{H_2}^0 H_2^\dagger H_2 - \frac{\bar{\lambda}}{2} \left( (H_1^\dagger H_1)^2 + (H_2^\dagger H_2)^2 + 2 H_1^\dagger H_1 H_2^\dagger H_2 \right).
\]

The bars indicate renormalized parameters with all fields canonically normalized, as in Eq. (16):

\[
\bar{m}_i^2 = \frac{m_i^2}{Z_i}, \quad \bar{\lambda} = \frac{32\pi^2}{N_c \log \left( \frac{M_{KK}^2}{\mu^2} \right)}, \quad \bar{g}_i = \bar{g} = \frac{4\pi}{\sqrt{N_c \log \left( \frac{M_{KK}^2}{\mu^2} \right)}},
\]

where the \(Z_i\)'s are the scalar wavefunction renormalization constants induced at low-energies. Here only the effects of the Yukawa interactions are shown, and the \(m_i\) are given by Eqs. (13) replacing the appropriate Yukawa couplings. An improved analysis that takes into account the effects of the gauge and quartic couplings is straightforward. As will become clear in the following, in the case of interest to us the RG improved analysis is identical to the analysis done in Subsection 2.5.

To simplify our discussion, we consider the following region of parameter space: \(c_Q \leq c_2 < c_1 < -1/2\), \(18\) which leads to an ordering of 4-fermion coefficients: \(g_{Q\chi R}^2 > g_{Qt}^2\) (with \(g_{\chi\chi\chi\chi}^2\) and \(g_{\chi\chi\chi}^2\) small and negative). Furthermore, we consider the case with \(g_{Q\chi R}\) slightly above the critical value \(G_c^2\) of the NJL model [see Eq. (14)]. Due to the relaxation mechanism discussed in Subsection 2.4 generically we have \(g_{Qt}\) below the critical value unless \(c_1\) is accidentally extremely close to \(c_Q\). Hence the vacuum of the potential should have \(\langle H_2 \rangle = 0\), and a nonzero VEV for \(H_1\). For this range of parameters, only \(H_1\) plays a role in stabilizing the radion. The radion potential is simply given by Eq. (15), changing \(H\) to \(H_1\):

\[
V(H_1, L) = \bar{m}_{H_1}^2(L) H_1^\dagger H_1 + \frac{\bar{\lambda}(L)}{2} (H_1^\dagger H_1)^2.
\]

The analysis to determine the VEV’s of \(H_1\) and \(L\) is the same as in Subsection 2.3.

After the EW symmetry is broken by \(\langle H_1 \rangle = v_{EW}\), \(t_L\) obtains a dynamical mass by marrying with the \(\chi_R’\) field. Including the Dirac mass of the light KK mode \(\chi\), the mass terms take the form \(\bar{g}_{Q\chi R} \langle H_1 \rangle t_L \chi_R' + \sin \alpha m_d \bar{\chi}_L t_R' + \cos \alpha m_d \bar{\chi}_L \chi_R' + \text{h.c.}\), which can be recognized as the “top

\(18\)We choose \(c_2 < c_1\) without loss of generality, since we can always relabel \(\Psi_1\) and \(\Psi_2\) to have a more negative Dirac mass for \(\Psi_2\). The assumption that \(c_Q\) is more negative than the other localization parameters ensures that the condensed bound state is a doublet under the \(SU(2)_L\) gauge group.
Figure 4: Left panel: the curve corresponding to $v_{EW} = 174$ GeV in the $c_2$-$c_Q$ plane. Right panel: the mass of the first KK gauge boson as a function of $c_2$ (the corresponding $c_Q$ on the curve of the left panel for a given $c_2$ is used).

"seesaw" structure. We find it more useful to consider the fermion mass matrix in the original KK basis $(t_R, \chi_R)$, rather than in the rotated basis $(t'_R, \chi'_R)$ that was useful in analyzing the physics of condensation. It reads

\[
\begin{pmatrix}
\bar t_L & \bar \chi_L
\end{pmatrix}
\begin{pmatrix}
-\sin \alpha \, \bar g_{QXR} \langle H_1 \rangle & \cos \alpha \, \bar g_{QXR} \langle H_1 \rangle \\
0 & m_d
\end{pmatrix}
\begin{pmatrix}
t_R \\
\chi_R
\end{pmatrix}.
\]

(50)

In the limit that the Dirac mass is large, $m_d \gg \bar g_{QXR} \langle H_1 \rangle$, the physical top quark mass is

\[
m_t^2 \approx \sin^2 \alpha \, (\bar g_{QXR} \langle H_1 \rangle)^2,
\]

(51)

while the mass of the extra colored physical quark field $\chi$ is

\[
m_{\chi}^2 \approx m_d^2 + \cos^2 \alpha \, (\bar g_{QXR} \langle H_1 \rangle)^2.
\]

(52)

In our model, we have 5 free parameters: $g_5$, $c_Q$, $c_1$, $c_2$ and $\theta$ to fit three observed quantities: $\alpha_s$, $v_{EW}$ and $m_t$. Since only $g_5$, $c_Q$ and $c_2$ enter the potential of $H_1$ and $L$, through $g_{QXR}^2 = g_{cQ} g_{c_2}$, we determine their values first by fitting $v_{EW}$ and $\alpha_s$. By minimizing the potential w.r.t. $H_1$ and $L$, we show in Fig. 4 the curve in the $c_Q$-$c_2$ plane corresponding to $\langle H_1 \rangle = v_{EW} = 174$ GeV. The mass of the first KK gluon $M_{KK}$ is around 35 TeV, as can be seen on the right panel of Fig. 4 and this result is stable against variations of the localization parameters that reproduce $v_{EW} = 174$ GeV, and insensitive to the precise value of the curvature $k$. In these figures, $k = 2 \times 10^{17}$ GeV and $\mu = v_{EW}$ are used. We also use the effective coupling $g_5 \sqrt{k} = 5.12$, which
is defined in Eq. (45) and calculated at the $M_{\text{KK}} \approx 35$ TeV scale by assuming the mass of the additional $\chi$ field to be around 2 TeV (see Subsection 4.2). The lower value of $c_2 \approx -0.60$ guarantees $c_Q < c_2$.

Having determined $c_Q$ as a function of $c_2$ from $v_{\text{EW}}$, we are left with three parameters $c_1$, $c_2$ and $\theta$ to fit the top quark mass. Substituting $m_t = 172.4$ GeV [35] and the RG improved value of $\bar{g}_{Q\chi R} \langle H_1 \rangle = 375$ GeV as discussed in Section 2.5 into Eq. (51), we see that $\sin \alpha \approx 0.46$. Then $\theta$ is determined as a function of $c_1$ and $c_2$ from Eq. (39) as $\tan \theta = -\tan \alpha \sqrt{\rho_{c_2}/\rho_{c_1}}$. Finally, only two free parameters, $c_1$ and $c_2$, are left to determine the spectrum of other particles in our model such as the heavy top quark, which is around 2 TeV to be compatible with electroweak precision observables, as discussed in Section 4.2.

The second doublet $H_2$ is heavier than the Higgs boson $h$ unless one fine-tunes $g^2_{Qt}$ to be extremely close to $g^2_{Q\chi R}$ so that it is also close to $G^2_c$. For a typical $c_1$, $m_{H_2}$ is around 10 TeV.

### 3.3 Light Fermion Masses

Since the 5D theory is non-renormalizable, 5D local 4-fermion operators are anticipated to exist in the bulk, e.g.

$$\mathcal{L}_5 \supset \frac{d_\xi}{\Lambda^3} (\bar{\Psi}_{\xi L} \Psi_{\xi R})(\bar{\Psi}_{Q L} \Psi_{2}) + \text{h.c.} + \cdots,$$

where $d_\xi$ is an unknown dimensionless coefficient, and $\Psi_{\xi L}$ and $\Psi_{\xi R}$ are 5D spinors with their zero modes $\xi_L$ and $\xi_R$ representing SM fermions (one of them is an $SU(2)_L$ doublet, the other one a singlet). Those operators involving only the top and $\Psi_2$ fields can be added to the 4-fermion interactions induced by gluon exchange discussed before. However, as argued in Appendix A, these contributions are expected to be a small correction compared to the gluon-induced ones. Hence, our analysis of the dynamical breaking of the EW symmetry, with the concomitant stabilization of the radion field, and the generation of the top mass is not expected to be affected much by such effects. Nevertheless, the local higher-dimension operators involving the other SM fermion fields would be responsible, in the present scenario, for giving rise to the remaining Yukawa interactions. Indeed, after integrating out the fifth dimension, Eq. (53) induces the following 4-fermion interactions in the 4D effective theory:

$$\mathcal{L}_4 \supset \frac{d_\xi}{(AL)^2 \Lambda^2} \bar{f}_{\xi L \xi R \chi_R Q_L} (\bar{\xi}_L \xi_R) (\bar{\chi}_R Q_L) + \text{h.c.} + \cdots,$$  

\footnote{Notice that KK gluon exchange does not induce “non-diagonal” operators of the form Eq. (53).}
where $\tilde{\Lambda} = \Lambda e^{-kL}$ is the warped down cutoff, $\xi_L$ and $\xi_R$ are the standard model fermions (zero modes) and

$$f_{\xi_L \xi_R \chi_L^\dagger Q_L} = \frac{1}{L} \int_0^L dy e^{-2k(L-y)} f_{\xi_L}(y) f_{\xi_R}(y) f_{Q_L}(y) \left[ \cos \alpha k_2(y) - \sin \alpha h_2(y) \right]$$

$$= -\frac{\sqrt{p_{\xi_L} p_{\xi_R} p_{Q_L}}}{\sqrt{p_{\xi_L} p_{\xi_R} p_{Q_L} p_{\xi_R}}},$$

with $f_i(y)$ and $p_i$ as defined in Eqs. (2) and (3), respectively, while $h_2(y)$ and $k_2(y)$ are given in Eq. (11).

In order to see how the Yukawa couplings between the $\xi$ fields and the Higgs arise consider an operator of the form Eq. (54) together with the $(g_{Q_{XR}}^2/M_{KK}^2)(\bar{Q}_L\chi_R)(\chi_R Q_L)$ operator in Eq. (14). In terms of the bilinears $B_1 = \bar{\xi}_L \xi_L$ and $B_2 = \bar{Q}_L \chi_R$, we simply have

$$\frac{d_\xi}{(\Lambda L)^2} f_{\xi_L \xi_R \chi_L^\dagger Q_L} B_1 B_2^\dagger + \frac{g_{Q_{XR}}^2}{M_{KK}^2} B_2 B_1^\dagger = \frac{g_{1}^2}{M_{KK}^2} \tilde{B}_1 \tilde{B}_1^\dagger + \frac{g_{2}^2}{M_{KK}^2} \tilde{B}_2 \tilde{B}_2^\dagger, \quad (55)$$

where $\tilde{B}_1 = \cos \gamma B_1 + \sin \gamma B_2$ and $\tilde{B}_2 = -\sin \gamma B_1 + \cos \gamma B_2$ are linear combinations that “diagonalize” the above 4-fermion interactions, and $g_1^2/M_{KK}^2$, $g_2^2/M_{KK}^2$ are the corresponding eigenvalues. To the extent that $d_\xi/(\tilde{\Lambda}^2 AL) f_{\xi_L \xi_R \chi_L^\dagger Q_L} \ll g_{Q_{XR}}^2/M_{KK}^2$, we have $g_1^2 \ll g_2^2 \approx g_{Q_{XR}}^2$ while the mixing angle is given by $\gamma \approx [d_\xi/(g_{Q_{XR}}^2 AL)](M_{KK}^2/\Lambda^2) f_{\xi_L \xi_R \chi_L^\dagger Q_L}$. Only the second 4-fermion interaction on the r.h.s. of Eq. (55) is sufficiently strong to lead to a condensate, exactly along the lines discussed in previous sections. Describing this process by the introduction of an auxiliary scalar field $H_1$, we end up with a Yukawa interaction of the form $\tilde{g}_{Q_{XR}} \tilde{B}_2 H_1 = -\tilde{g}_{Q_{XR}} \sin \gamma \bar{\xi}_L \xi_R \chi_L H_1 + \bar{Q}_L \chi_R \cos \gamma \bar{Q}_L \chi_R H_1$, where $\tilde{g}_{Q_{XR}}$ is the running Yukawa coupling at a scale $\mu$, as discussed in Subsection 2.3. Therefore, the $\xi$ Yukawa coupling is

$$y_\xi = \frac{\tilde{g}_{Q_{XR}} d_\xi M_{KK}^2}{g_{Q_{XR}}^2 (\Lambda L)^2} f_{\xi_L \xi_R \chi_L^\dagger Q_L} \approx \frac{N_c \tilde{g}_{Q_{XR}} d_\xi M_{KK}^2}{8\pi^2 (\Lambda L)^2} f_{\xi_L \xi_R \chi_L^\dagger Q_L}, \quad (56)$$

where in the second equality we used $g_{Q_{XR}}^2 \approx 8\pi^2/N_c$. This expression has a simple interpretation as a one-loop diagram obtained by an insertion of the operator Eq. (54), where the $\chi_R Q_L$ lines are closed with the Yukawa interaction $\tilde{g}_{Q_{XR}} \bar{Q}_L H_1 \chi_R$ discussed in Eq. (17). This one-loop diagram is quadratically divergent, and should be cutoff at the scale $M_{KK}$. Up to order one factors this gives rise to a Yukawa coupling of the order of Eq. (56). Notice that the fact that the one-loop integral is dominated by the $M_{KK}$ scale suggests evaluation of $\tilde{g}_{Q_{XR}}$ at $\mu \sim M_{KK}$. Nevertheless, even at lower scales, $\tilde{g}_{Q_{XR}}/g_{Q_{XR}} \approx (375/174)/\sqrt{8\pi^2/N_c} \approx 2/5$ [see Fig. 3] so that
no significant changes of the previous estimate arising from these details are expected. Notice also that operators similar to Eq. (53) but involving $\Psi_1$ instead of $\Psi_2$ do not contribute to the Yukawa coupling.

It is useful to have approximate expressions for the above Yukawa couplings, taking into account the fact that $Q_L$ and $\chi'_R$ are localized close to the IR brane (since these fields are assumed to have the strongest interactions with the KK gluons, thus triggering EWSB by a bifermion condensate). For light SM fermions $\xi$ localized near the UV brane, we have

$$y_{\text{light}} \approx \frac{N_c \bar{g}_{Q\chi_R} d_{\xi} M_{\text{KK}}^2}{8\pi^2} \frac{(1 - 2c_Q)(1 - 2c_2)(1 - 2c_{\xi_L})(1 - 2c_{\xi_R})}{4 - c_Q - c_2 - c_{\xi_L} - c_{\xi_R}} \left(\frac{(1 - c_{\xi_L} - c_{\xi_R})k_L}{(\Lambda L)\tilde{\Lambda}^2} e^{(1 - c_{\xi_L} - c_{\xi_R})k_L}\right),$$

(57)

where, as discussed in the next section, $c_Q \sim -2/3$, $c_2 \sim -1/2$. In order to estimate the unknown coefficient $d_{\xi}$ we resort to NDA which, as shown at the end of Appendix A, gives $d_{\xi}^{\text{NDA}} \sim 24\pi^3/n$, where $n \lesssim 45$. Taking also $\Lambda \sim 10k$ and $M_{\text{KK}} = 2.45\tilde{k}$, the $c$-independent factor in Eq. (57) times $v = 174$ GeV evaluates to $\sim 64$ GeV/n, which shows that the light fermion masses can be accommodated by an appropriate choice of $c_{\xi_L}, c_{\xi_R} > 1/2$.

For the bottom quark, which has $c_{\xi_L} = c_Q$ [the localization parameter for the $(t_L, b_L)$ doublet], we need to take $c_{\xi_R} \equiv c_{b_R} < 1/2$, in which case

$$y_{\text{bottom}} \approx \frac{N_c \bar{g}_{Q\chi_R} d_{b} M_{\text{KK}}^2}{8\pi^2} \frac{M_{\text{KK}}^2}{(\Lambda L)\tilde{\Lambda}^2} \frac{(1 - 2c_Q)(1 - 2c_2)(1 - 2c_{b_R})}{4 - 2c_Q - c_2 - c_{b_R}}(1 - c_{\xi_L} - c_{\xi_R})k_L.$$

(58)

For $c_Q \sim -2/3$, $c_2 \sim -1/2$ and, for example, $c_{b_R} = 0$, with the other parameters as above, this leads to a mass $m_b \sim 36$ GeV/n. Given the uncertainties in the estimate of the unknown coefficient $d_b$, we conclude that it is not implausible that the bottom mass also arises from the above 4-fermion interactions.

### 4 Phenomenology

Our model predicts two new particles beyond the SM model, besides a heavy Higgs boson $h$ with a mass around 500 GeV. They are a light radion field at the GeV scale and an extra colored heavy fermion $\chi$ with a mass in the TeV range. We will study constrains on new particle masses due to LEP bounds and electroweak precision observables, and discuss their phenomenological consequences in this scenario in turn.
4.1 The Radion

At tree-level in the 5D theory, the radion-dependent terms arise from the 5D Einstein-Hilbert action. The corresponding low-energy 4D action, with a canonically normalized radion reads \[ S = \frac{M_5^2}{k} \int d^4x \sqrt{-g} \left( 1 - \frac{\phi^2}{F^2} \right) R + \frac{1}{2} \int d^4x \sqrt{-g} \{ \partial_{\mu} \phi \partial^{\mu} \phi - V(H_1, -k^{-1} \ln \phi/F) \} , \tag{59} \]

where \( \phi(x) \equiv F e^{-kT(x)} \) with \( \langle T \rangle = L \) and \( F = \sqrt{12M_5^4/k} \). Since the 4D Planck mass is \( M_P^2 \approx M_5^3/k \approx (2 \times 10^{18} \text{ GeV})^2 \), we have \( F \approx 2\sqrt{3} M_P \approx 6.9 \times 10^{18} \text{ GeV} \). Unless otherwise specified, we take \( M_5 \sim 10^{18} \text{ GeV} \) and \( k = 2 \times 10^{17} \text{ GeV} \). Eq. (59) also contains the Higgs-radion potential of Eq. (19). As explained in previous sections, this determines dynamically \( \langle H_1 \rangle = v_{\text{EW}} \) and \( \langle T \rangle = L \). Writing \( H_1 = v_{\text{EW}} + \frac{1}{\sqrt{2}} \bar{h} \) and \( \phi = \bar{F} + \varphi \), with \( \bar{F} = F e^{-kL} \), Eq. (19) leads to the Higgs-radion mass matrix:

\[
\frac{1}{2} (h \varphi / \bar{F}) \left( \begin{array}{cc}
-\sqrt{\frac{2}{g^2}} m_{H_1}^2(l) & \sqrt{\frac{2}{g^2}} m_{H_1}^2(l) v'_{\text{EW}}(l) \\
\sqrt{\frac{2}{g^2}} m_{H_1}^2(l) v'_{\text{EW}}(l) & -4m_{H_1}^2(l)v'_{\text{EW}}(l)^2 + \frac{1}{2} \left( m_{H_1}^2(l)v_{\text{EW}}(l)^2 \right)''
\end{array} \right) \left( \begin{array}{c}
h \\
\varphi / \bar{F}
\end{array} \right) ,
\]

where we used \( v_{\text{EW}}^2 = -m_{H_1}^2/\bar{\lambda} \), defined \( l \equiv kL \), and it is understood that all the entries are evaluated at the minimum of the potential, \( l_{\text{min}} = kL_{\text{min}} \) [see Eq. (23)]. We see that, in general, there is mass mixing between the radion and the Higgs boson. However, since \( \langle \phi \rangle = \bar{F} \gg v_{\text{EW}} \), the mixing angle is extremely small. For the benchmark point discussed in Section 3 with \( c_2 = -0.535 \) and \( c_Q = -0.675 \), we have \( \langle \phi \rangle = 490 \text{ TeV} \), and the mixing angle is approximately \( 1.3 \times 10^{-5} \) which can be neglected.\(^{20}\) Therefore, the Higgs boson mass \( m_h \) is still as determined in the improved RG analysis of Subsection 2.2 around 500 GeV. The mass of the radion is \( m_{\varphi}^2 \approx \frac{1}{2} \left[ m_{H_1}^2(l)v_{\text{EW}}(l)^2 \right]/\bar{F}^2 \approx (0.4 \text{ GeV})^2 \), where the terms proportional to \( v_{\text{EW}}(l)^2 \) are subdominant and can be neglected. Note that the radion mass is of order \( v_{\text{EW}}^2/\bar{F} \). The denominator \( \bar{F} \) is related to the spontaneously broken conformal symmetry; the numerator is related to the explicit breaking of the conformal symmetry, since the electroweak scale is different from zero only when the localization parameters are away from the conformally invariant limit \( c_Q = c_2 = 1/2 \).

To have a better estimate of the allowed radion masses in our model, we vary the 5D curvature in the window \( k \in (1 \times 10^{17}, 2 \times 10^{18}) \text{ GeV} \), and adjust \( M_5 \) so as to keep the 4D Planck

\(^{20}\)Higgs/curvature mixing as first discussed in [37] would arise from a higher-dimension bulk operator in the 5D theory that involves four fermion fields and the Ricci curvature scalar, where the fermions bilinears are replaced by the effective Higgs degrees of freedom at energies below the KK scale. The resulting coefficient in the 4D theory is therefore expected to be suppressed at least by order \( (k/\Lambda)(M_{KK}/\Lambda)^4 \), which makes it unlikely to be relevant for phenomenology.
mass $M_P$ unchanged. For each $k$, we first determine the allowed values of $c_Q$ and $c_2$ to have the correct $v_{	ext{EW}}$, and then calculate the radion and Higgs boson masses. Since $(g^2_{Q\chi R} - G^2_c)/G^2_c \ll 1$ at the minimum of the potential, the mass of the radion takes the approximate form

$$m_\phi \approx \frac{3 x_1 \tilde{f}_2 k M_{\text{KK}}}{64 \pi^3 \log^2 \left( \frac{x_1}{M_{\text{KK}}} \right) \log^2 \left( \frac{M_{\text{KK}}}{\mu} \right) M_P} \approx \frac{k}{M_P} (4 \text{ GeV}), \quad (60)$$

where $\tilde{f}_2$ was defined in Eq. (22) and $x_1 \approx 2.45$. The mass of the Higgs boson and the mass of the first KK gluon do not vary much when $k$ is varied, and they are still around 500 GeV and 35 TeV respectively. In the left panel of Fig. 5 the radion mass is shown as a function of $k$. As can be seen, $m_\phi$ is a linear function of $k$ and is around a few GeV in the above window for $k$. In the right panel of Fig. 5, the radion VEV $\langle \phi \rangle = \tilde{F}$ is shown as a function of $k$, and, for $k/M_P < 0.5$, is of order a few hundred TeV.

The radion field couples to ordinary matter via the energy-momentum tensor, and its couplings are inversely proportional to the scale invariance (spontaneous) symmetry breaking scale. In more detail [38],

$$\mathcal{L}_{\text{int}} = \frac{\phi}{\langle \phi \rangle} \left[ \sum_\psi F_{c_\psi} m_\psi \bar{\psi} \psi + M_Z^2 Z^\mu Z_\mu + 2 M_W^2 W^+ \mu W^- \mu + \frac{\beta(g_s)}{2 g_s} G^{\alpha \mu \nu} G_{\alpha \mu \nu} + \frac{\beta(e)}{2 e} F^{\mu \nu} F_{\mu \nu} \right],$$

where $F_{c_\psi}$ is a function that depends on the fermion localization parameter, and $\beta(g_s)$ and $\beta(e)$ are the QCD and QED beta functions, taking all fermions lighter than the radion into account. LEP imposes bounds on the couplings of a light scalar to $Z$ gauge bosons [39]. For the radion,
these couplings are controlled by the ratio $v_{EW}/\langle \phi \rangle$, which in our case is a few $\times 10^{-4}$. This is below the current LEP upper bound on this ratio, which is about $10^{-1}$.

4.2 Electroweak Precision Constraints and Spectrum

The oblique parameters $S$ and $T$ constrain the remaining two model parameters $c_1$ and $c_2$ ($c_Q$ has already been determined by $v_{EW}$, $\theta$ is determined by $m_t$, and $g_5$ is determined by $\alpha_s$). The $U$ parameter in our model is much smaller than the $S$ and $T$ parameters, and is neglected in the following. In Appendix B we give the formulas for $\Delta T$ and $\Delta S$ in our model, defined as the deviations of $T$ and $S$ from the standard model with a Higgs boson mass of 117 GeV. The dominant contribution to $\Delta S$ comes from the heavy Higgs of mass 450-500 GeV. The heavy fermions give a smaller contribution, and we have $\Delta S \approx 0.08$ for a wide range of choices of $c_1$ and $c_2$. A two-parameter fit to the EW data with a reference mass of $m_h = 117$ GeV requires $0.04 < \Delta T < 0.23$ for $\Delta S = 0.08$, at the 95% CL.\footnote{The fit does not include low-energy data, but the latest measurements of $m_W = 80.432 \pm 0.039$ GeV and $m_t = 172.4 \pm 1.2$ GeV at the Tevatron are included in the fit. We thank Jens Erler for kindly providing the fit results, which we have reproduced with good agreement using the code in [40].} In Fig. 6 we show the allowed region of

Figure 6: Left panel: curves of constant $\Delta T$ in the $c_1$-$c_2$ plane. The two thick (red) lines demarcate the allowed region at the 95% CL. In this analysis we assumed $c_1 > c_2$ (see footnote), and therefore we show the complementary region in gray in the plots. Right panel: curves of constant $\Delta S$ in the $c_1$-$c_2$ plane, showing that the region in the left panel has $\Delta S \approx 0.08$.
parameter space that satisfies the electroweak constraints. We impose $c_1 < c_2$, as discussed in Subsection 3.2. We also use $m_h = 475$ GeV and $\bar{g}_{Q,R} \langle H_1 \rangle = 375$ GeV as described in Section 2.5. The left panel of Fig. 6 shows a contour plot of the $T$ parameter as a function of $c_1$ and $c_2$. The curves of constant $\Delta T$ are most sensitive to $c_2$ and are only mildly dependent on $c_1$. This is because, for fixed $\bar{g}_{Q,R} \langle H_1 \rangle$, the Dirac mass $m_d$ controls the mixing of the left-handed top quark with the fermion $SU(2)_L$ singlet—which dominantly determines the contribution to $\Delta T$ from the fermion loops—and $m_d$ is mainly controlled by $c_2$. Since the 475 GeV Higgs boson contributes $\sim -0.2$ to $\Delta T$, a positive and non-negligible contribution from fermion loops is necessary to bring the $T$ parameter back to the experimentally allowed region. Therefore, there is an upper bound on the Dirac mass $m_d$ (via an upper limit on $c_2$). In the right panel of Fig. 6, we show a contour plot for the $S$ parameter as a function of $c_1$ and $c_2$, showing that $\Delta S \approx 0.08$ in the region of interest (the 475 GeV Higgs boson contributes $\sim -0.07$ to $\Delta S$ while $\chi$ contributes $\sim 0.01$). There are also tree-level contributions to the $S$ and $T$ parameters that arise when the heavy KK gauge bosons are integrated out, but for $M_{KK} \approx 35$ TeV these are one order of magnitude smaller than the fermion and Higgs boson loop-level contributions, and are not included in the plots.

Notice that in our setup the $(t_L, b_L)\ SU(2)_L$ doublet is extremely localized towards the IR brane, thus triggering EWSB through the condensate. As mentioned above, the KK scale is dynamically set to be about $M_{KK} \approx 35$ TeV, which corresponds to $\tilde{k} \equiv k e^{-kL} \approx 14$ TeV. This high scale allows localizing the light families close to the UV brane—so that the fermion mass hierarchies arise from wavefunction localization effects—without inducing large anomalous contributions to the $Zb_L b_L$ coupling due to mixing with the heavy KK gauge bosons. In fact, assuming that the light fermions are localized near the UV brane, we have

\[
\frac{\delta g_{b_L}^{\text{tree}}}{g_{b_L}} \approx -\frac{e^2}{s_w^2 c_w^2} \frac{v_{EW}^2}{k^2} \frac{(4c_Q^2 - 16c_Q + 7)kL}{8(4c_Q^2 - 16c_Q + 15)} \quad c_Q \to \infty \quad -\frac{e^2}{s_w^2 c_w^2} \frac{v_{EW}^2}{k^2} \frac{kL}{8} .
\]

For $v_{EW} = 174$ GeV, $\tilde{k} \approx 14$ TeV and $kL \approx 30$, one finds $\delta g_{b_L}^{\text{tree}}/g_{b_L} \approx -3 \times 10^{-4}$. There is also a loop-level correction to the $Zb_L b_L$ vertex induced by the vector-like quark $\chi$ through its mixing with the top quark. In the limit that $\chi$ is much heavier than the top quark, we have

\[
\delta g_{b_L}^{\text{loop}} \approx \frac{e^2}{64\pi^2 s_w^2 M_W^2} \left( \bar{g}_{Q,R} \langle H \rangle \cos \alpha \langle H \rangle \right)^4 \left[ 1 + 2 \frac{m_t^2}{(\bar{g}_{Q,R} \langle H \rangle \cos \alpha \langle H \rangle)^2} \left( \log \frac{m_{b_L}^2 - 1}{m_t^2} \right) \right] ,
\]

\[
\frac{22}{22}\text{We assume that the EW breaking VEV is effectively localized on the IR brane. A more detailed analysis that takes into account the fact that the fermionic Higgs constituents have profiles that extend into the extra dimension most likely will reduce this estimate even further.}
Figure 7: The mass of the $\chi$ field as a function of $\Delta T$. The dashed line is for the central value of $\bar{g}_{QX_R}\langle H_1 \rangle = 375$ GeV, while the thick lines are for 350 GeV and 400 GeV, respectively [adjusting the angle $\alpha$ to keep $m_t$ fixed, see Eq. (50)]. The variation of the Higgs mass in the 450–500 GeV range changes the curves only slightly.

which gives\textsuperscript{23} $\delta g_{b_L}^{\text{loop}}/g_{b_L} \approx -2.4 \times 10^{-3}$ for $m_\chi = 2$ TeV (see below), $\bar{g}_{QX_R}\langle H \rangle = 375$ GeV and $\alpha = 0.48$. Adding the tree-level and loop-level contributions, one has $\delta g_{b_L}/g_{b_L} \approx -2.7 \times 10^{-4}$, which is comparable to the current experimental bound. Moreover, the dominant contributions to $\Delta T$ and $\delta g_{b_L}$ depend on the same underlying model parameters (but are essentially uncorrelated with $S$). Nevertheless, we have checked that the 95% CL ellipsoid resulting from a simultaneous fit to $S$, $T$ and $\delta g_{b_L}$, using the code in \cite{40}, results in essentially the same allowed range in $\Delta T$ as discussed above. Therefore, the additional constraints from $\delta g_{b_L}$ turn out to be very mild.

The constraints from EW observables discussed above in the $c_1$-$c_2$ plane allow us to constrain the mass of the vector-like fermion $\chi$. For $c_2$ less than but not too close to $c_1$, so that $e^{-(c_1-c_2)kL} \ll 1$, we obtain an approximate expression for $m_\chi$, which is almost independent of $c_1$:

$$m_\chi \approx \sqrt{4c_2^2 - 1 \sec \alpha e^{(c_2+1/2)kL \tilde{k}}}$$ (63)

Recall that $\alpha \approx \arcsin m_t/(\bar{g}_{QX_R}\langle H \rangle) \approx 0.48$ for $\bar{g}_{QX_R}\langle H \rangle = 375$ GeV. This approximate formula for $m_\chi$ holds for $m_d \gg \bar{g}_{QX_R}\langle H_1 \rangle$ and is within 5% of the exact value. In Fig. 7 we show the mass of the $\chi$ field as a function of $\Delta T$. The contribution to $\Delta T$ due to the $\chi$ fermion depends on the Dirac mass $m_d$ and the mixing with the top quark which is governed by $\bar{g}_{QX_R}\langle H_1 \rangle$ [see

\textsuperscript{23}We thank José Santiago for pointing out a missing factor in Eq. (62) of an earlier version.]
Eq. (50). The dashed line corresponds to the central value $g_{Q\chi R}\langle H_1 \rangle = 375$ GeV. The band corresponds to the variation of $g_{Q\chi R}\langle H_1 \rangle$ between 350 GeV and 400 GeV. We adjust the angle $\alpha$ to reproduce the top mass $m_t$, and also take into account its effect, through $\theta$, on $m_d$ [see Eqs. (36) and (39), although we do not use the approximate expression (36) but instead solve the exact eigenvalue equation to obtain $m_d$]. We see that the electroweak constraints determine $m_\chi$ to be between 1.6 and 2.9 TeV.

4.3 Collider Phenomenology

In this section, we explore the prospects for discovery of the heavy Higgs boson and the new colored fermion at the LHC. After diagonalization of Eq. (50), we obtain the top and heavy fermion mass eigenstates with their masses given by Eqs. (51) and (52). As discussed above, our model has definite predictions for their masses. To simplify the notation, from now on we shall denote the fermion mass eigenstates as $t$ and $\chi$. The relevant interactions of $h$ and $\chi$ with other particles in unitary gauge are

$$
\mathcal{L}_{\text{int}} \supset \frac{e}{s_W c_W} Z_\mu \left[ \bar{t}_L \gamma^\mu \left( \frac{1}{2} c_{\beta_L}^2 - s_{\beta_L}^2 Q_t \right) t_L + \bar{\chi}_L \gamma^\mu \left( \frac{1}{2} c_{\beta_R}^2 - s_{\beta_R}^2 Q_\chi \right) \chi_L 
+ \bar{\chi}_L \gamma^\mu \left( \frac{1}{2} s_{\beta_L} c_{\beta_L} \right) t_L + \bar{t}_L \gamma^\mu \left( \frac{1}{2} s_{\beta_R} c_{\beta_R} \right) \chi_L - s_{\beta_L}^2 W_t \bar{t}_R \gamma^\mu t_R - s_{\beta_R}^2 W_\chi \bar{\chi}_R \gamma^\mu \chi_R \right]
+ \frac{e}{\sqrt{2} s_W} W^+_\mu \left( c_{\beta_L} \bar{t}_L \gamma^\mu b_L + s_{\beta_L} \bar{\chi}_L \gamma^\mu b_L \right) + \frac{e}{\sqrt{2} s_W} W^-_\mu \left( c_{\beta_R} \bar{b}_L \gamma^\mu t_L + s_{\beta_R} \bar{\chi}_L \gamma^\mu \chi_L \right)
+ \frac{m_t}{\sqrt{2} v_{\text{EW}} s_\alpha} h \left( c_{\beta_L} s_{\beta_R - \alpha} \bar{t}_L t_R + s_{\beta_L} c_{\beta_R - \alpha} \bar{\chi}_L \chi_R + c_{\beta_L} c_{\beta_R - \alpha} \bar{t}_L \chi_R + s_{\beta_L} s_{\beta_R - \alpha} \bar{\chi}_L t_R + \text{h.c.} \right),
$$

(64)

where $Q_t = Q_\chi = 2/3$ are the top and $\chi$ electric charges and $s_{\beta_{L,R}} \equiv \sin \beta_{L,R}$ with $\beta_{L,R}$ the left- and right-handed mixing angles obtained from diagonalization of the fermion mass matrix, Eq. (50). The exact formula for $\beta_L$ is given in Eq. (75), but for $m_\chi \gg g_{Q\chi R}\langle H_1 \rangle$ we have the simple result $\beta_L \approx (m_t/m_\chi) \cot \alpha$. For $\alpha = 0.48$, $g_{Q\chi R}\langle H_1 \rangle = 375$ GeV and $m_\chi = 2$ TeV we have $\beta_L \approx 0.16$. The right-handed mixing angle is $\beta_R \approx 0$ for the same set of parameters. We note here that deviations of the top Yukawa coupling from its SM value are of order $m_t^2/m_\chi^2$, which, for the above parameters, results in a decrease of about 2%.

The Higgs boson in our model has a mass around 475 GeV, and is heavy enough to decay into a pair of $W$ gauge bosons, $Z$ gauge bosons or top quarks. Taking the running of fermion
masses into account, a SM Higgs of mass 475 GeV has a total width of $\Gamma_h^{total} \approx 56.6$ GeV, and the branching ratios of the three main decay channels are $Br(h \rightarrow \bar{t}t) \approx 19.5\%$, $Br(h \rightarrow W^+W^-) \approx 54.5\%$ and $Br(h \rightarrow ZZ) \approx 26.0\%$, respectively [42, 43]. In our model, the changes of those branching ratios from their SM values are of order $m_t^2/m_\chi^2$ due to the deviation of the top Yukawa coupling from its SM value, and are negligible. Unlike a light Higgs, a heavy Higgs boson mainly decays to gauge bosons due to the enhancement of its decays into the longitudinal components of the gauge bosons as its mass gets larger.

At the LHC, the dominant production of the Higgs boson is through gluon fusion. The new quark $\chi$, is too heavy and has too small a coupling to the Higgs boson (its mass gets only a small contribution from the EWSB) to contribute appreciably to the Higgs boson production. Compared to the Higgs boson in the SM with the same mass, the production rate from the top quark contribution is suppressed by at most a few percent due to a slightly smaller top Yukawa coupling. At next-to-next-to-leading-order in QCD, the SM cross section to produce a 475 GeV Higgs boson at the LHC is about 7 pb [44, 45, 46]. For values of the Higgs mass around 475 GeV, the decay $h \rightarrow ZZ \rightarrow 4\ell$ is the “gold-plated” mode for discovery at the LHC [47].

We also predict a new colored fermion $\chi$ that mixes with the top quark and has a mass in the window 1.6 to 2.9 TeV. Since $\chi$ is much heavier than the other particles in the SM, the Goldstone boson equivalence theorem implies

$$\Gamma(\chi \rightarrow t h) = \Gamma(\chi \rightarrow t Z) = \frac{1}{2} \Gamma(\chi \rightarrow b W) = \frac{\cot^2 \alpha m_\chi^2}{64 \pi v^2} m_\chi.$$ \hspace{1cm} (65)

The total width of $\chi$ is approximately 140 GeV for $m_\chi = 2$ TeV. Independently of the mass of the $\chi$ field, as long as it is large, it decays to $b W$ with a 50% branching ratio, and to $t h$ and $t Z$ with an equal branching ratio of 25%.

The strength of the single $\chi$ production rate is governed by $g_{\chi_L b_L W}$, which relates to $g_{t_L b_L W}$ by $g_{\chi_L b_L W}/g_{t_L b_L W} = \tan \beta_L \approx 0.16$. The single $\chi$ production rate is larger than the pair production rate by more than two orders of magnitude when the $\chi$ mass is around 2 TeV [48, 49, 50]. Therefore, single $\chi$ production through the process $q b \rightarrow q^\prime \chi$ provides the best discovery channel at the LHC. Existing studies on new top-like quarks at the LHC show that the $\chi$ field can be discovered up to $m_\chi = 2.5$ TeV with 300 fb$^{-1}$ luminosity at a 5$\sigma$ significance [50] by studying the decay chain $\chi \rightarrow b W \rightarrow \ell \nu b$. This covers a wide range of the expected values of $m_\chi$ in this scenario. Specific to our model, the decay chains $\chi \rightarrow h t \rightarrow ZZ W b, 3 W b$.

\hspace{1cm} $^{24}$The coupling among $\chi, b$, and $W$ in our model can be mapped to the $\lambda_1/\lambda_2 = 2$ case in [50].
and $3W3b$ would provide interesting signal topologies for the presence of the heavy quark and Higgs boson, and deserve more careful studies at the LHC.

5 Conclusions

We have considered the intriguing possibility that there may exist a deep connection between two of the known fundamental scales in nature: the Planck and the EW scales. Our framework is based on the observation that the existence of a warped extra-dimension can provide such a deep link through the dynamical determination of the ratio between the two scales. As a byproduct, a third scale, the scale of KK resonances, is dynamically fixed in this model.

The scenario we envision is as follows: there are no fundamental scalars, and the 5D version of the SM (without a Higgs) is supplemented by a single $SU(2)_L$ singlet 5D fermion without zero-modes. The EW symmetry is broken as a consequence of top condensation, which results from the strong interactions associated with the lightest KK gluon resonance. In the low-energy theory there appears an effective Higgs degree of freedom with a mass of about 500 GeV and SM-like properties. The fact that the top mass is of order the EW scale is understood as a result of the prominent role the top plays in the breaking of the EW symmetry, as in Topcolor [18] and top seesaw [12] scenarios. Our main observation is that the physics that leads to condensation automatically induces a potential that stabilizes the distance between the UV and IR branes (described by a radion field). Thus, the large hierarchy between the Planck and EW scales is determined dynamically. Interestingly, when the radion relaxes to the minimum of the potential induced by EW symmetry breaking, the KK scale is determined to be about two orders of magnitude above the EW scale. Our analysis was performed in the large $N$ approximation, but we identified the basic ingredients behind the mechanism, which may hold beyond this approximation. Additional calculable contributions to the radion potential may be suppressed in the presence of additional fermionic degrees of freedom that need not interact with the SM fields. The non-calculable contributions to the radion potential are assumed to be suppressed in a way not necessarily related to EWSB. If this is not the case, the little hierarchy between $M_{KK}$ and $v_{EW}$ may not survive.

The prediction that the KK scale is parametrically larger than the electroweak scale allows the scenario to be consistent with EW precision constraints, since corrections due to the KK physics are appropriately suppressed. The negative contribution to the Peskin-Takeuchi $T$ parameter from the 500 GeV Higgs can be compensated by the contribution from a relatively
light vector-like quark that mixes with the top quark. In particular, the mass of this new fermion is expected to be between 1.6 and 2.9 TeV, and should be observable at the LHC via single production for most of its expected range. A light radion field with a mass of order a few GeV is also predicted, although its observation is expected to be challenging since it couples weakly to SM matter. Summarizing, the Higgs will be accessible at the LHC with a few fb$^{-1}$ or less, although it will be rather difficult to distinguish it from a SM Higgs. Deviations from the SM in the $h t\bar{t}$ coupling of order 2%, which would induce small variations in the gluon fusion Higgs production and in the Higgs branching fractions, will be most likely beyond the LHC sensitivity given theoretical and experimental uncertainties. This small variation could be probed at a future lepton collider. The new light vector-like fermion with mass in the 1.6 – 2.9 TeV range will require LHC integrated luminosities above 100 fb$^{-1}$, and would be the first direct new physics signal of this scenario beyond the SM.

It is perhaps somewhat disappointing that the physics ultimately responsible for the radion stabilization mechanism (the KK states) lies beyond the reach of the LHC. On the other hand, the feature that the KK states are rather heavy, might be counted as a success from the point of view of EW precision tests. Notice, however, that the discovery of a vector-like quark with a mass in the TeV range might be taken as indication for the existence of an extra dimension that plays a role in EWSB. A 500 GeV Higgs could suggest the presence of strong dynamics. Our scenario would represent an example of a theory that defies the commonly held expectations that new TeV-scale particles responsible for the cancellation of quadratic divergences in the Higgs boson mass parameter should be present. In the model described in this paper, both the loop contributions to the Higgs mass parameter and the “bare” Higgs mass are of order the KK scale. But the dynamics of our scenario, through their radion dependence, leads to a cancellation between these two contributions, resulting in a Higgs mass of order the electroweak scale.

We also stress that localization of fields in the extra-dimension plays a unifying role in this scenario. The fermions that condense are the two most closely localized near the IR brane. The radion stabilization mechanism drives their 4-fermion interaction strength down, leaving it slightly above criticality and triggering condensation. On the other hand, 4-fermion couplings associated with other fermions not so close to the IR brane are reduced, generically lie below the critical value and do not lead to additional bi-fermion condensates. This makes our scenario distinct from previous extra-dimensional realizations of EWSB via fermion-anti fermion condensation [15, 16]. The effective Higgs degree of freedom can be thought as being localized
near the IR brane, in the sense that its fermion constituents are. In addition, we showed how all fermion masses other than the top mass can arise from “fundamental” 4-fermion interactions. This results in a scenario where the observed fermion mass hierarchies and flavor structure can be obtained from the localization of the fermions along the extra-dimension, realizing the picture of flavor from anarchy. It is interesting that the same higher-dimensional mechanism of fermion localization can be at the heart of the physics of flavor and EWSB. We find it remarkable that this simple setup can provide rather non-trivial connections among the physics of gravity, EWSB and flavor.

Acknowledgements

We thank Thomas Appelquist, Bogdan Dobrescu, Christopher Hill, Markus Luty and Carlos Wagner for useful comments, and in particular Bill Bardeen for illuminating discussions. E.P. wishes to thank the Fermilab Theory Group for hospitality during various stages of this work. Fermilab is operated by Fermi Research Alliance, LLC under contract no. DE-AC02-07CH11359 with the United States Department of Energy. E.P. was supported by DOE under contract DE-FG02-92ER-40699.

A Validity of the Effective Theory

In the main text we analyzed the low-energy physics associated with the 4-fermion interactions that arise when the KK gluons are integrated out at tree-level. In order for the condensate to form, this coupling needs to be supercritical, hence in the strong-coupling regime. One might then wonder about the reliability of the above results, in particular as regards the radion potential. In this appendix we clarify the precise sense in which the theory is strongly coupled, and argue that the 5D UV cutoff is 10 times the curvature scale \( k \) and is essentially independent of the fermion zero-mode localization parameter \( c \).

We start by discussing the relation between the two scales \( M_{\text{KK}} \) and \( \tilde{\Lambda} = \Lambda e^{-kL} \), and arguing that they are indeed distinct, with \( \tilde{\Lambda} \gg M_{\text{KK}} \), in spite of the strong coupling that participates in the condensation mechanism. The important point to realize is that the supercritical coupling, Eq. (10), is obtained by means of localizing the fermion zero-modes very close to the IR brane, not by increasing the 5D gauge coupling \( g_5 \).\(^{25}\) Furthermore, the localization affects almost

\(^{25}\)In fact, if we identify \( g_5 \) with the gauge coupling associated with the SM strong interactions, \( g_5 \) is of similar
exclusively the fermion zero-mode. The fermion KK modes become somewhat heavier when the zero mode is localized closer to the IR brane, while their couplings are rather insensitive to the value of $c$. For instance, if we concentrate on the physics at the IR brane, where couplings are largest, the KK mode wavefunctions obey $|f_n(L)| \approx \sqrt{2kL}$, essentially independent of $c$. Recall that, in the KK picture, the large values of these wavefunctions are precisely the reason that the KK modes are more strongly coupled than the zero mode. What is happening as $c$ becomes more negative is that the couplings of the zero mode increase roughly like $\sqrt{(1/2 - c)kL}$, and can become as large as those of the KK modes. It follows that only those observables that are IR dominated, hence potentially sensitive to the fermion zero-mode, can be sensitive to the value of $c$. On the contrary, observables that are UV dominated do not depend on $c$. This observation will be important when estimating the unknown coefficients of various operators in the underlying 5D theory.

It is instructive to understand the above statements in terms of the fermion propagator in the mixed position/momentum space representation. Considering a fermion with a LH zero-mode, the propagator describing the zero-mode tower takes the form $G_{LL}(y, y') = iP_L y' G_p(y, y')$, where $p$ is the 4-momentum. The exact result for this propagator is given in Eq. (24) of Ref. [51]. When considering UV sensitive loops, only the case with $y = y'$ is relevant (non-local effects have an associated Yukawa suppression that ensures they are finite). For illustration purposes we concentrate on the physics near the IR brane, so that $y = y' = L$. In this case, one finds in Euclidean space,

$$G_p(L, L) \approx \frac{e^{4kL}}{p} \left[ \frac{1 - c(c+1)}{p^2} \frac{k}{2p} \right] \to \frac{e^{4kL}}{p} = \lim_{\Lambda \to \infty} \int_{-\Lambda}^{\Lambda} \frac{dp}{p} \frac{e^{4kL}}{p^2 + p^2},$$

(66)

where $\tilde{k} = k e^{-kL}$, and the first approximation is excellent for $p \geq \tilde{k}$ and $|c| \leq 1$, which contains the region of interest. We see, as indicated by the arrow, that as soon as $p$ becomes a few times larger than $\tilde{k}$, the propagator attains its 5D behavior, which is not only independent of $c$ but, as expected, is also identical to the flat space result (the warp factors simply combine to redshift the mass scales appropriately). Thus, UV sensitive loops can be estimated as in flat size as in standard RS scenarios with bulk fields (or slightly smaller since one has to match to the 4D gauge coupling at a KK scale of order tens of TeV, as opposed to a few TeV.)

---

26This formula is a reasonable approximation for $-1 < c < 0$. As $c \to -\infty$, the coupling turns to $\sqrt{2kL}$.

27We define the propagators as the inverse of the relevant quadratic operator, $O_\phi$, including warp factors: $\sqrt{\mathcal{O}_\phi} G = i\delta$. The mixed position/momentum space Feynman rules for the vertices contain also the appropriate warp factors. For instance, for the fermion gauge interactions, one should use $\int dy e^{-3ky} i g_5 \gamma^\mu$, for $\mu = 0, \ldots, 3$. 

38
space and are independent of the strong interactions associated with the zero mode when it is localized near the IR brane.

With the above understanding, we proceed to estimate the cutoff of the 5D theory. We define the scale $\Lambda$ as the lowest scale where an interaction gets strong, understood as the scale where the loop expansion breaks down (adding a loop to a diagram by using the interaction in question does not lead to a suppression). For instance, the fermion one loop contribution to the gluon self-energy is

\[ \sim \int dy A_\mu(q, y) P^{\mu\nu} A_\nu(q, y') N_f g_5^2 \int \frac{d^4 p}{(2\pi)^4} G_p(y, y') G_{p+q}|y'| \]

where $N_f$ is the number of flavors [in the fundamental representation of $SU(N_c)$], and we used that gauge invariance requires the result to be proportional to $P^{\mu\nu} = q^\mu q^\nu - q^2 \eta^{\mu\nu}$. In the second line we used the fact that the propagator $G_p(y, y')$ decays exponentially over distances of order $1/p$, and that the momentum integral is dominated by $p \sim \Lambda$, so that $y'$ is required to be within $1/\Lambda$ of $y$. Using Eq. (66) for $y = L$, removing the trivial warp factor, and using the indicated cutoff $\Lambda$ (which corresponds to a truncation of the KK sums), we have $G_p(L, L) = 2 \arctan(\Lambda/p)/\pi p$. Using this result, the parenthesis in the above diagram evaluates to $N_f g_5^2 \Lambda/(12\pi^3)$. Notice that the above careful computation using the propagator (66) leads to the same result that one would have obtained in an uncompactified 5D theory. The NDA estimate for $g_5$ then corresponds to

\[ g_5^2 \sim \frac{l_5}{N \Lambda}, \]  

(67)

where $l_5 = 24\pi^3$ is the 5D loop factor\footnote{Although in this one-loop diagram one gets a loop factor suppression of $12\pi^2$, in general the “natural” variable in the momentum integrals is $p^2 + p_5^2$, which leads us to define the generic loop factor with an additional factor of $1/2$ \cite{52}. Of course, NDA should be taken with a grain of salt at this level of precision.} and we replaced $N_f \rightarrow N \equiv |\frac{2}{3}N_f - \frac{5}{3}N_c|$ to take into account the diagrams involving the $SU(N_c)$ self-interactions. Matching to the 4D coupling constant, $g_4^2 = g_5^2/L$, we get

\[ \Lambda L \sim \frac{l_5}{N g_4^2}. \]  

(68)
This result holds both in flat and warped spaces. In warped space, however, we are interested in the relation between $\Lambda$ and $k$:

$$\frac{\Lambda}{k} \sim \frac{l_5}{k L N g_4^2},$$

which for $kL \sim 30$ and $g_4 \sim 0.9$ gives $\Lambda/k \sim 30/N$. If we consider the SM strong interactions with the SM field content then $N_f = 2 \times 6 = 12$, $N_c = 3$ and $N = 3$, so that $\Lambda/k \sim 10$. This is large enough for the propagators to attain their asymptotic 5D behavior and validates the previous analysis, in particular that divergent integrals can be estimated as in a flat, uncompactified 5D theory. We stress that this estimate is essentially independent of the strong localization of certain light fields towards the IR brane, and the validity of the 5D theory is as well justified as in other RS scenarios with SM fields in the bulk.

Having established that the cutoff $\Lambda$ is well above the KK scale, we can estimate the coefficients of various operators in the underlying 5D theory. In the main text, we considered the effects of 4-fermion operators induced at the KK scale. However, one can also write directly 4-fermion operators in the 5D theory:

$$L_5 \supset \frac{d_{ijkl}}{\Lambda^3} (\bar{\Psi}_i \Gamma \Psi_j)(\bar{\Psi}_k \Gamma \Psi_l),$$

where the $\Gamma$’s are arbitrary matrices and the indices $i,j,\ldots$ run over all the fermions. These include the $N_f$ quark flavors as well as any additional $SU(N_c)$ singlets (leptons). Considering the one-loop self-renormalization of the 4-fermion interactions, and assuming that the dimensionless coefficients $d_{ijkl} \sim d$ are all of the same order, we estimate

$$\sim \sum_{i,j,k,l} \frac{1}{l_5} \frac{d_{ijmn}d_{klmn}}{\Lambda^3} \sim \left(\frac{n d}{l_5}\right) \frac{d}{\Lambda^3}.$$

Comparing to the tree-level 4-fermion interaction, we see that the NDA estimate for $d$ is $l_5/n$, where $n$ counts the number of diagrams that can contribute to the loop. The 4-fermion interaction also renormalizes the gluon self-energy considered above, e.g.

$$\sim \left(\frac{N_f d}{l_5}\right) \left(\frac{N_f g_5^2}{l_5} \Lambda q^2\right),$$

where we indicated schematically the dependence on the external momentum required by gauge invariance. Using the NDA estimate for $d$, we see that this contribution is suppressed compared
to the diagrams that do not involve the 4-fermion interaction by a factor $N_f/n$, which is typically much smaller than one. We therefore see that the gauge interactions are expected to be stronger than the 4-fermion interactions and should be used to estimate the cutoff $\Lambda$, as done above. It is easy to check that this picture holds at higher loop orders.

We can now estimate the size of the above 4-fermion interactions in the low-energy 4D theory:

$$\mathcal{L}_4 \supset \frac{d f_{ijkl}}{(\Lambda L)^2} \langle \bar{\psi}_i \Gamma \psi_j \rangle \langle \bar{\psi}_k \Gamma \psi_l \rangle,$$

where $\tilde{\Lambda} = \Lambda e^{-kL}$, and $f_{ijkl} = (1/L) \int dy e^{2k(y-L)} f_{c_i} f_{c_j} f_{c_k} f_{c_l}$ contains the dependence on the zero-mode wavefunctions given in Eq. (2). For the fermions that are localized near the IR brane, one has $f_{ijkl} \approx \left[ \frac{(1/2 - c)^2}{(1-c)} \right] kL$, where we took, for simplicity, a common localization parameter $c$. Thus, this 4-fermion operator is suppressed compared to (4) by $d f_{ijkl} g_{\psi} \left( \frac{M_{KK}}{\tilde{\Lambda}} \right)^2 \approx g_4^4 (3 - 2c) \left( \frac{N^3}{n} \right) \left( \frac{kL}{l_5} \right)^2 kL,$

where we used the leading order term for $g_{\psi}^2 = g_{c_1} g_{c_2}$ from Eq. (10), with $c_1 = c_2 = c$, and the NDA estimates for $g_{\psi}^2$, $d$ and $\Lambda$ discussed above. Using $kL \approx 30$, $c \sim -1/2$, $N = 3$, this gives a suppression $\sim 3.5/n$. The number of contributing diagrams, $n$, depends on the type of operator we are considering. For instance, for the operators considered in Subsection 3.3 that are responsible for giving masses to the fermions other than the top: $(Q_1 L f_2 R)(Q_3 L f_4 R)$ where the $Q_i$’s are $SU(2)_L$ doublets and the $f_i$’s are $SU(2)_L$ singlets, we typically have $n = 3 \times 4 \times N_c + 3 \times 3 = 45$ [the first term counts quarks, three doublets and four singlets including the additional $\chi$ field, the second counts the leptons]. We therefore see that these incalculable effects are expected to be subdominant in regards to the physics that leads to fermion condensation. However, notice that these 4-fermion operators can be included in the analysis of condensation and radion stabilization together with those induced by KK gluon exchange. They simply correspond to adding a new (small) contribution to the $c$-dependent function of Eq. (4), $f_1(c_1, c_2)$, while leaving $f_2(c_1, c_2)$ in (8) unchanged [see the expression for $f_{ijkl}$ above Eq. (72), or also Eq.(58)]. Thus, the mechanism described in the main text is expected to change only in small details.

### B The $S$ and $T$ parameters

In this appendix we collect the formulas for the contributions to the $S$ and $T$ parameters in our model, $\Delta S$ and $\Delta T$. These are defined as the deviation from the SM with a fixed reference Higgs
mass. There are two main sources for non-zero $\Delta S$ and $\Delta T$: one from the vector-like $SU(2)_L$ singlet fermion that mixes with the LH top, and a second one from the fact that the Higgs field in our model is heavier than the reference value. The latter effect gives a contribution

$$\Delta S_h = \frac{1}{12\pi} \log \left( \frac{m_h^2}{m_{h_{\text{ref}}}^2} \right),$$

$$\Delta T_h = -\frac{3}{16\pi \cos^2 \theta_W} \log \left( \frac{m_h^2}{m_{h_{\text{ref}}}^2} \right),$$

(73)

where $m_{h_{\text{ref}}} = 117$ GeV is the reference Higgs boson mass, and $\theta_W$ is the weak mixing angle. The contribution due to the fermion loop is

$$\Delta T_f = \frac{3 s_{\beta_L}^2}{16\pi \sin^2 \theta_W \cos^2 \theta_W} [W_1(y_t, y_b) - W_1(y_t, y_b) - c_L^2 W_1(y_t, y_t)] ,$$

$$\Delta S_f = \frac{3 s_{\beta_L}^2}{2\pi} [W_2(y_t, y_b) - W_2(y_t, y_b) - c_L^2 W_3(y_t, y_t)] ,$$

(74)

where $y_t \equiv m_t^2/M_Z^2$, and $s_{\beta_L}$, $c_{\beta_L}$ are short notations for $\sin \beta_L$ and $\cos \beta_L$, with $\beta_L$ the mixing angle of the LH top quarks:

$$\beta_L = \frac{1}{2} \arctan \frac{2 \cos \alpha m_d \bar{g}_{Q_X} \langle H_1 \rangle}{m_d - \bar{g}_{Q_X} \langle H_1 \rangle^2},$$

(75)

obtained by diagonalization of Eq. (50). Here the functions $W_1$, $W_2$ and $W_3$ are defined by

$$W_1(y_1, y_2) \equiv y_1 + y_2 - \frac{2 y_1 y_2}{y_1 - y_2} \log \frac{y_1}{y_2},$$

$$W_2(y_1, y_2) \equiv \frac{22 y_1 + 14 y_2}{9} - \frac{1}{9} \log \frac{y_1}{y_2} + \frac{11 y_1 + 1}{18} W_4(y_1, y_1) + \frac{7 y_2 - 1}{18} W_4(y_2, y_2),$$

$$W_3(y_1, y_2) \equiv \frac{y_1 + y_2}{2} - \frac{(y_1 - y_2)^2}{3} + \left( \frac{(y_1 - y_2)^3}{6} - \frac{1}{2} \frac{y_1^2 - y_2^2}{y_1 - y_2} \right) \log \frac{y_1}{y_2} + \frac{y_1 - 1}{6} W_4(y_1, y_1) + \frac{y_2 - 1}{6} W_4(y_2, y_2),$$

(76)

with

$$W_4(y_1, y_2) \equiv \begin{cases} -2\sqrt{\Delta} \left( \arctan \frac{y_1 - y_2 + 1}{\sqrt{\Delta}} - \arctan \frac{y_1 - y_2 - 1}{\sqrt{\Delta}} \right) & \Delta > 0 \\ \sqrt{-\Delta} \log \frac{y_1 + y_2 - 1 + \sqrt{-\Delta}}{y_1 + y_2 - 1 - \sqrt{-\Delta}} & \Delta \leq 0 \end{cases},$$

(77)

and

$$\Delta = -1 - y_1^2 - y_2^2 + 2 y_1 + 2 y_2 + 2 y_1 y_2 .$$

(78)
Other than $W_2$, all $W_i(y_1, y_2)$ are symmetric functions under the interchange of the variables $y_1$ and $y_2$.

While both the Higgs and fermion loops give a positive contribution to $\Delta S = \Delta S_h + \Delta S_f$, the contribution to $\Delta T = \Delta T_h + \Delta T_f$ from the Higgs boson is negative and can be compensated by the positive contribution due to the fermions. In our model, since $M_{\text{KK}} \approx 35$ TeV is much larger than the electroweak scale, we neglect the tree-level contributions to the $T$ and $S$ parameters that arise when the KK gauge bosons are integrated out. Other contributions to the $T$ parameter coming from purely LH 4-fermion interactions, as discussed in [55], are negligible.
