Abstract. – Taking into account stress fluctuations due to thermal noise, we study thermally activated irreversible crack growth in disordered media. The influence of material disorder on sub-critical growth of a single crack in two-dimensional brittle elastic material is described through the introduction of a rupture threshold distribution. We derive analytical predictions for crack growth velocity and material lifetime in agreement with direct numerical calculations. It is claimed that crack growth process is inhibited by disorder: velocity decreases and lifetime increases with disorder. More precisely, lifetime is shown to follow a super-Arrhenius law, with an effective temperature \( \theta - \theta_d \), where \( \theta \) is related to the thermodynamical temperature and \( \theta_d \) to the disorder variance.

Introduction. – Sub-critical rupture occurs when a material is submitted to a stress lower than a critical threshold. It is known since the early work of Zhurkov or Brenner [1, 2] that sub-critical rupture can be thermally activated. However, prediction of the lifetime, i.e. the time it takes for a sample to break under a given load, has proved difficult when the material is heterogeneous. In addition, although there have been several theoretical attempts to predict the lifetime for homogeneous [3–5] and sometimes disordered [6, 7] elastic materials, there have been very few theoretical studies of the actual rupture dynamics in heterogeneous media when thermal activation is the driving mechanism [8–10]. Recently, this dynamics has been modelled for a single macroscopic crack in two-dimensional homogeneous elastic media taking into account stress fluctuations [11]. This model has been successfully faced with experiments of crack growth in fax paper sheets even though this material is actually heterogeneous [12]. In the present letter, we will take into account heterogeneity by introducing, in the thermal activation rupture model, disorder in the rupture thresholds. We will show that disorder slows down macroscopic crack growth contrary to previous results [8,9] that show the rupture dynamics to be accelerated by disorder in the case of diffuse damage.

Model for sub-critical crack growth in homogeneous brittle media. – In ref. [11], the model that describes sub-critical crack growth in homogeneous brittle media assumes that thermal
fluctuations induce local stress fluctuations with time in the elastic material according to a gaussian distribution:

\[ p(\sigma) = \frac{1}{\sqrt{2\pi\theta}} \exp \left( -\frac{(\sigma - \bar{\sigma})^2}{2\theta} \right), \tag{1} \]

with \( \theta \) the temperature in square stress unit: \( \theta = Yk_BT/V \), where \( Y \) is the Young modulus, \( k_B \) the Boltzmann constant and \( T \) the thermodynamical temperature. In eq. (1), \( \bar{\sigma} \) is the equilibrium value of the stress \( \sigma \) fluctuating in a volume \( V \). We assume the volume \( V \) to break if the fluctuating local stress \( \sigma \) becomes larger than a critical threshold \( \sigma_c \). In the two-dimensional case where a single crack is loaded in mode 1 (uniaxial stress perpendicular to the crack direction), stress concentration makes almost certain that breaking occurs at the crack tip. Actually, at the crack tip, linear elasticity predicts a divergence of the stress. However, the average elastic stress \( \sigma_m \) on a volume \( V \sim \lambda^3 \) at the crack tip does not diverge and can be estimated as:

\[ \sigma_m(\ell) = \frac{2\sigma_e\sqrt{\ell}}{\sqrt{2\pi\lambda}}, \tag{2} \]

where \( \ell \) is the crack length and \( \sigma_e \) the applied stress. The local stress on the crack tip volume \( V \) is submitted to time fluctuations according to eq. (1) with \( \sigma = \sigma_m(\ell) \).

The cumulative probability that the instantaneous crack tip stress is larger than the threshold \( \sigma_c \) is \( P(\sigma_c) = \int_{\sigma_c}^{+\infty} p(x) \, dx \). Then, the average time \( \langle t_w \rangle \) needed by the crack tip material to break on the mesoscopic scale \( \lambda \) is directly proportional to the inverse of this cumulative probability: \( \langle t_w \rangle = t_0/P(\sigma_c) \), where \( t_0 \) is a characteristic time for stress fluctuations. The statistically averaged inverse crack velocity, \( dt/d\ell \), is constructed as the ratio of the average time \( \langle t_w \rangle \) over the growth length due to rupture at each tip of the crack, \( dt/d\ell = \langle t_w \rangle/2\lambda \). Then,

\[ \frac{dt(\ell)}{d\ell} = \begin{cases} \frac{1}{v_0 \operatorname{erfc} \left( \frac{\sigma_c - \sigma_m(\ell)}{\sqrt{2}\theta} \right)} & \text{if } \sigma_c - \sigma_m(\ell) \geq 0 \\ \frac{1}{v_0} & \text{if } \sigma_c - \sigma_m(\ell) < 0 \end{cases} = \frac{1}{v_h(\sigma_m(\ell), \sigma_c, \theta)}, \tag{3} \]

with \( v_0 = \lambda/t_0 \). For critical crack growth, i.e. when \( \sigma_m(\ell) > \sigma_c \), the crack simply propagates at its characteristic dynamical velocity: \( dt/d\ell = 1/v_0 \).

This model was successfully used to describe the growth of a single crack in a fibrous material such as paper [12]. In that case, the scale \( \lambda \) corresponds to the typical paper fiber diameter. However, paper is heterogeneous and distributions in fiber size, position or orientation introduce some disorder which has not been taken into account in this model.

**Model extension for disordered media.** – Many brittle materials are heterogeneous at a mesoscopic scale. Crack front roughness is one evidence for this heterogeneity. To introduce some disorder in the model, we assume the rupture threshold of the material, \( \sigma_c \), to be distributed at the scale \( \lambda \) with a gaussian distribution:

\[ p_{\text{th}}(\sigma_c) = \frac{1}{\sqrt{2\pi\theta_d}} \exp \left( -\frac{(\sigma_c - \bar{\sigma}_d)^2}{2\theta_d} \right) \text{ for } \sigma_c \geq 0, \tag{4} \]

with a variance verifying \( \sqrt{\theta_d} \ll \bar{\sigma} \) so that the distribution can be considered normalized. For sake of simplicity, we will consider the crack to grow on a straight line and introduce disorder effects only through the threshold distribution. Then, it is clear that, during its growth, the crack is faced, in statistical average, with the whole intrinsic threshold distribution of the material. The relevance of this simplification will be discussed in the last section.
Using the threshold distribution of eq. (4) at the crack tip, a new expression for the statistical average of the inverse crack velocity can be written:

\[
\frac{dt}{d\ell} = \int_0^{+\infty} \frac{p_{th}(\sigma_c) d\sigma_c}{v_h(\sigma_m(\ell), \sigma_c, \theta)},
\]

where \(v_h\) is the crack velocity for the homogeneous case. Here, the inverse velocity, \(1/v_h\), is weighted by the threshold distribution because the waiting time for the crack to grow by a fixed step \(\lambda\) is the statistical variable. Assuming \(\sigma_c - \sigma_m \gg \sqrt{\theta} + \sqrt{\theta_d}\), the integrand in eq. (5) takes significative values only for a range of \(\sigma_c\) such that: (i) \(\sigma_c - \sigma_m \geq 0\) and the integral can be truncated from \(\sigma_m\) to \(+\infty\); (ii) the energy barrier \((\sigma_c - \sigma_m)^2/2\theta\) can be considered far larger than one so that an asymptotic development of the complementary error function can be introduced in eq. (5). After rearrangement, we obtain:

\[
\frac{dt}{d\ell} \sim \frac{\sigma_c - \sigma_m}{\theta - \theta_d} v_0 \frac{1}{\sqrt{2(\theta - \theta_d)}} \exp \left[ \frac{(\sigma_c - \sigma_m)^2}{2(\theta - \theta_d)} \right].
\]

Then, we can estimate the integral:

\[
\int_{\sigma_m}^{+\infty} (\sigma_c - \sigma_m)e^{-\frac{\theta_0 \theta_d}{2\theta_d}(\sigma_c - \sigma_m)^2} d\sigma_c = \int_{\sigma_m}^{+\infty} (\sigma_c - \sigma_m + \sigma_\theta - \sigma_m)e^{-\frac{\theta_0 \theta_d}{2\theta_d}(\sigma_c - \sigma_\theta)^2} d\sigma_c
\]

\[
= \left[ -\frac{\theta_0 \theta_d}{\theta - \theta_d} e^{-\frac{\theta_0 \theta_d}{2\theta_d}(\sigma_c - \sigma_\theta)^2} \right]_{\sigma_m}^{+\infty} + (\sigma_\theta - \sigma_m) \int_{\sigma_m}^{+\infty} e^{-\frac{\theta_0 \theta_d}{2\theta_d}(\sigma_c - \sigma_\theta)^2} d\sigma_c.
\]

Here, it is important noticing that both terms of eq. (8) are infinite when \(\theta < \theta_d\). So, it is clear that, in the case where \(\theta < \theta_d\), the inverse crack velocity and the rupture time will become infinite. On the other hand, considering the case where \(\theta > \theta_d\), we get:

\[
\frac{dt}{d\ell} \sim \frac{\theta}{\theta - \theta_d} \frac{1}{v_0} \sqrt{\frac{\pi}{2(\theta - \theta_d)}} (\sigma_c - \sigma_m) \exp \left[ \frac{(\sigma_c - \sigma_m)^2}{2(\theta - \theta_d)} \right].
\]

Eq. (9) corresponds, with an additional prefactor \(\theta/(\theta - \theta_d)\), to the asymptotic development of eq. (8) for the homogeneous case introducing an effective temperature \(\theta_{eff} = \theta - \theta_d\). Then, eq. (9) can be seen as an approximation of:

\[
\frac{dt}{d\ell} \sim \frac{\theta}{\theta - \theta_d} \frac{1}{v_h(\sigma_m(\ell), \sigma_c, \theta - \theta_d)}, \quad \text{when } \theta > \theta_d.
\]

The conclusion of this part is that crack velocity is lowered by the introduction of disorder in the model material, mainly through the appearance of a lowered effective temperature \(\theta_{eff} = \theta - \theta_d\) in place of the thermodynamical temperature \(\theta\). The variance \(\theta_d\) can then be seen as a temperature of disorder.

**Direct numerical analysis of the model.** In order to check the validity of eq. (10), we study numerically the model starting from eq. (5). In fig. (11), we plot \((\theta - \theta_d)/\theta (dt/d\ell)_{num}\), obtained by numerical calculation of eq. (5)’s right hand side, as a function of the crack length for a set of particular values for the model parameters. The analytical law, \(y = 1/v_h(\sigma_m(\ell), \sigma_c, \theta_{eff})\), fits very well the numerical data using \(\theta_{eff}\) as a fitting parameter.
It is clear as one can see in fig. (b) that the effective temperature $\theta_{eff}$ obtained from the numerical data fits corresponds very well to the one predicted analytically, $\theta_{eff} = \theta - \theta_d$, when $\theta$ and $\theta_d$ are both varying. However, the coincidence of the numerical $\theta_{eff}$ with $\theta - \theta_d$ is not perfect. Numerical $\theta_{eff}$ is actually perfectly described by $\theta_{eff} = a(\theta_d)(\theta - \theta_d)$ with $a$ ranging from 1 to 1.014 when $\theta_d$ increases from 0 to 0.004 ($\overline{\sigma}_c = 1$). These numerical results confirm the good quality of eq. (10) even if it is the result of approximate calculations.

**Rupture time.** We will now go a step further in the analysis of our model by studying the rupture time dependence with the model parameters. When there is no disorder, rupture time is defined as the time for a crack of initial length $\ell_i$ to grow until it reaches a critical length $\ell_c$ such that $\sigma_m(\ell_c) = \sigma_c$. In paper [11], we got an approximate expression of the mean rupture time for homogeneous systems assuming some approximations in eq. (3):

$$\tau \simeq \frac{\sqrt{2\pi(\ell_i)}}{\theta_0\sigma_i} e^{\frac{(\sigma_c - \sigma_i)^2}{2\theta}} = \tau_{o} e^{\frac{(\sigma_c - \sigma_i)^2}{2\theta}}$$

where $\sigma_i = \sigma_m(\ell_i)$. \hspace{1cm} (11)

This law has been tested experimentally on the slow growth of a single crack in fax paper sheets [12]. It is shown that statistically averaged crack growth curves are in good agreement with the model predictions as well as the lifetime dependence on applied stress, initial crack length and Young modulus.

Back on the calculations of paper [11], we easily get an analytical expression for the mean lifetime in the heterogeneous case from eq. (3):

$$\tau \simeq \frac{\theta}{\sqrt{\theta - \theta_d}} \frac{\sqrt{2\pi(\ell_i)}}{\theta_0\sigma_i} e^{\frac{(\overline{\sigma}_c - \sigma_i)^2}{2(\theta - \theta_d)}} = \tau_{o}^{des} e^{\frac{(\overline{\sigma}_c - \sigma_i)^2}{2(\theta - \theta_d)}}$$

when $\theta > \theta_d$. \hspace{1cm} (12)

We note that the lifetime is super-Arrhenius. Fig. 2 shows the logarithm of the lifetime, obtained by numerical integration of eq. (5) and rescaled respectively by $\tau_{o}$ (on the left) and by $\tau_{o}^{des}$ (on the right) as a function of the energy barriers ($\overline{\sigma}_c - \sigma_i)^2/2\theta$ (on the left) and $(\overline{\sigma}_c - \sigma_i)^2/2(\theta - \theta_d)$ (on the right). Eq. (11) does not rescale the data when $\theta_d$ is varied. But, it is clear that the rescaling by eq. (12) makes all the data for different $\theta$ and $\theta_d$ fall
Fig. 2 – On the left: logarithm of the rupture time as a function of the energy barrier \( (\sigma_c - \sigma_i)^2 / 2\theta \) for many different growth conditions (0.005 \( \leq \theta \leq 0.25 \) and \( 5 \times 10^{-7} \leq \theta_d \leq 0.004 \)); on the right: logarithm of the rupture time as a function of \( (\sigma_c - \sigma_i)^2 / 2(\theta - \theta_d) \) for the same numerical data.

very well on the \( y = x \) straight line. This confirms the relevance of eq. (12) which predicts an increase of the lifetime with \( \theta_d \). Once again, analytical and numerical calculations confirm the deceleration of the crack growth due to disorder.

Facing the results with previous theoretical works. – The results presented in this letter differ from previous theoretical works on one-dimensional Disordered Fiber Bundle Model (1d-DFBM) describing the influence of disorder on the fracturing process [7–10]. In this model, as long as the critical fraction of broken fibers is less than 50% [10], the introduction of a threshold distribution actually accelerates rupture with an effective temperature larger than the thermodynamical temperature. The rupture process starts from the weaker fibers and progressively affects the stronger ones. As a result, the distribution of breaking thresholds is truncated from below by a front moving with time towards higher thresholds. Because rupture can occur everywhere in the system, this dynamics is non-local and the damage rate is given by how many fibers break at each time step. Consequently, the effect of disorder is obtained by averaging the damage rate over the threshold distribution. This is not at all the process which occurs when a large crack propagates in a disordered system. Here, the probability of breaking at the crack tip is greatly enhanced by stress concentration effects even for a large disorder. Then, the rupture dynamics becomes local, and one needs to average over disorder the time to break the fiber at the crack tip, i.e. the inverse of the damage rate. Finally, it is worth noticing that there are similarities between our model for crack growth predicting a super-Arrhenius rupture time and the trap model introduced by Bouchaud [13] to describe dynamics in glassy systems.

Discussion on the straight line growth hypothesis. – In our analysis, we assumed the crack to grow on a straight line even if roughness is experimentally observed for sub-critical cracks in heterogeneous materials. Is this hypothesis relevant for crack growth in heterogeneous materials? Two viewpoints can be raised.

One could think that roughness is due to the fact a crack, at each moment, grow in the direction where the material is the weakest. In this case, the crack, during its growth, will not experience the intrinsic threshold distribution of the material, but only a part of this
distribution that corresponds mainly to the lowest thresholds. Then, the distribution to be used in eq. (4) is not the intrinsic threshold distribution of the material.

But, one could also think that crack growth occurs in the direction where the stress intensification is the largest. Statistically, the larger the stress, the higher the probability to grow in the corresponding direction. This idea is supported by recent theoretical and experimental works [14, 15]. In this framework where the crack tip stress distribution rules the roughness, it is fair to consider the intrinsic threshold distribution of the material to rule the crack growth.

Experimental reality is probably a compromise between the two competing mechanisms: growth governed by stress intensification and growth following the path through the weakest regions. In the case of a material with a mesoscopic structure, such as paper, the crack tip is surrounded by a finite number of fibers so that the crack can grow only in a finite number of directions. The determination of the growth direction is clearly due the competition between stress intensification on each fiber compared to its toughness. It is worth noticing that crack tip structure complexity can create a complex stress distribution. Consequently, the largest stress is not necessarily in the crack main direction so that roughness can appear even if the crack always grows in the maximum stress direction.

Some numerical work has been performed to illustrate a situation where the crack is allowed to "choose" between a finite number of growth directions. We model a two-dimensional elastic system as a network of springs forming a lattice. More details about the simulations are given in [11]. The only discrepancies with the simulations presented there are the use of a hexagonal lattice instead of the previously used square lattice and the introduction of a rupture threshold distribution. We can see in fig. 3 that the crack can actually "choose" between three directions

![Fig. 3 – Geometry of the hexagonal spring lattice of the numerical simulation with a non-straight crack.](image)

(socalled upper, straight and lower directions) at each step. In fig. 3 a typical crack pattern after a thermally activated growth is presented. We can notice that the crack grows almost straight. Actually, the stress intensification on the upper and lower springs is only about 80% of the one of the straight spring. So, the crack will grow through the springs on the sides only if the rupture threshold of the straight spring is very large. This is only a rare event and we can say that the crack experiences essentially the intrinsic threshold distribution truncated of the very large thresholds only. In this simulation, the crack path is mainly ruled by stress intensification. Experimentally, the number of fibers joining at the crack tip can be larger than three so that variations in stress intensification between fibers are probably smoother than in the simulation.

No definitive conclusion on the growth process can be given because, depending on the considered material, one of the two competing mechanisms (growth governed by stress intensification and growth following the path through the weakest fibers) will dominate. The
results presented in this letter hold essentially for media where the crack path is ruled by stress intensification.

**Conclusion.** – Assuming the existence of thermal stress fluctuations in the material, we modelled sub-critical crack growth in disordered materials. The influence of material disorder on the growth of a single crack in two-dimensional brittle elastic material is described through the introduction of a rupture threshold distribution. Analytical predictions of the crack velocity and material lifetime have been derived in agreement with direct numerical calculations. The conclusion is that the crack growth process is inhibited by disorder: velocity decreases and lifetime increases with the temperature of disorder $\theta_d$. The influence of disorder is simply accounted for by introducing an effective temperature $\theta_{\text{eff}} = \theta - \theta_d$ for thermodynamical temperatures above $\theta_d$. Hence, lifetime follows a super-Arrhenius law. More experimental work is needed to confirm this super-Arrhenius regime. In addition, the analogy with glassy systems suggests that the growth of a crack in a disordered material could also occur in a "glassy" regime, i.e. when $\theta < \theta_d$.
