Abstract.
In the emerging quantum internet, complex network topology could lead to efficient quantum communication and enhanced robustness against failures. However, there are some concerns about complexity in quantum communication networks, such as potentially limited end-to-end transmission capacity. These challenges call for model systems in which the feasibility and impact of complex network topology on quantum communication protocols can be explored. Here, we present a theoretical model for complex quantum communication networks on a lattice of spins, wherein entangled spin clusters in interacting quantum spin systems serve as communication links between appropriately selected regions of spins. Specifically, we show that ground state Greenberger–Horne–Zeilinger clusters of the two-dimensional random transverse Ising model can be used as communication links between regions of spins, and we show that the resulting quantum networks can have complexity comparable to that of the classical internet. Our work provides an accessible generative model for further studies towards determining the network characteristics of the emerging quantum internet.
1. Introduction

The creation of a global quantum communication network to serve as a quantum internet is a highly anticipated goal that would enhance the existing classical internet, with applications in secure communications, quantum computation, distributed sensing, and more [1–4]. Experimental advances toward the technology needed for a quantum internet, such as quantum repeaters, are rapidly being made [5–12]. Such advances have already enabled the creation of quantum communication networks with a few nodes, which may be precursors to the future quantum internet [2, 13–15].

In the simplest case of quantum repeater based architectures, quantum communication networks can be represented as shown in Figure 1a [16–22]. Each node of the network represents a collection of quantum bits, or qubits, and each link of the network represents an entangled pair of qubits belonging to two distinct nodes. As such, the degree of each node (the number of links it has) is at most the number of qubits in the node. Quantum routing protocols based on entanglement swapping can generate entanglement between nodes which were initially not adjacent in the network, thereby enabling quantum communication between remote pairs of nodes within the network [17, 20–24].

Complex network topology is an emergent property observed in diverse real world networks. Complex networks prominently exhibit a heavy-tailed degree distribution, approximated by a power-law as

\[ P(k) \propto k^{-\gamma} \]

(1)

with \( 2 < \gamma < 3 \), where \( k \) is the degree of the node and \( P(k) \) is the fraction of nodes having degree \( k \) [25]. Another key feature of network complexity is the small-world property, stating that other nodes can be reached in a few steps from any given node: the diameter \( d \) of the network (the maximum shortest path length between any two nodes) increases slower than a power-law, for example \( d \propto \ln N \) for a network of \( N \) nodes. Complex topology has been shown to be essential to the proper functioning of the classical internet, for instance by making it robust to the random failure of computers or routers [26].

Recent findings highlight the need to investigate the possibility of complex topology in a quantum internet. For example, complex quantum communication networks exhibit promising robustness to random failures of noisy quantum-repeater nodes [27] (though in the different framework of quantum spin models on imprinted networks, complexity does not necessarily provide robustness [28]). Additionally, satellite-based quantum networks naturally have the small world property, meaning only a few entanglement swaps are needed to enable communication between any pair of nodes [29]. This is advantageous due to reduced usage of quantum resources. Another advantage to complex topology is that existing optical cables of the classical internet could be utilized for quantum communication, likely as part of a hybrid architecture along with more expensive cryocables, thus providing incentive to eventually match (at least partially) the complex topology of the classical internet [4–6, 30].
Complex quantum network models from spin clusters

Figure 1. Creation of quantum networks using spin clusters. a) Quantum communication networks based on quantum repeaters consist of collections of local qubits (orange nodes) that are entangled (green links) with qubits in other local collections. b) We propose the use of entangled clusters (green) in interacting spin systems as communication channels between nodes that are spatially localized regions of lattice sites (orange). c) Nodes are chosen as adjacent circular regions of sites from a broad size distribution, as illustrated here on a lattice of size 128 × 128. A link is added when a cluster in the underlying spin system is shared by exactly two nodes. d) The resulting network between nodes in panel c) indicates which pairs of nodes share entanglement. e) Using larger lattices (here 4096 × 4096), a complex network emerges. f) A snapshot of the classical internet from 1999 at the level of autonomous systems [31] shows similar complexity to that in panel e), although being significantly larger.

However, there are also anticipated difficulties with creating quantum communication networks that mimic the complexity of the classical internet. For one, unlike in the case of satellite-based quantum networks, quantum networks based on optical fibers do not necessarily have the small world property due to photonic losses limiting transmission length [32]. There are also concerns that low network densities of complex networks may limit end-to-end transmission capacity of quantum information, and that there is vulnerability to targeted attacks, just as in the classical internet [33, 34]. By default, existing proposals for the creation of quantum communication networks avoid
these issues by imposing a simple, grid-like network structure [1, 3]. Further, existing quantum routing protocols often assume simple grid-like or ring-like network structure [17, 20, 21, 23], with Ref. [24] as a recent exception. As such, there is a need for model systems in which the impact of complex topology on quantum communication can be studied.

In this paper, we present a proof-of-concept model to create quantum networks of substantial complexity in the context of spins on a lattice. As building blocks, we consider entangled spin clusters of interacting quantum spin models on a two-dimensional lattice, where the ground state factorizes into independent spin clusters (corresponding to magnetic domains). Our work is in part inspired by Ref. [35], where the author studied superconductivity by viewing clusters as nodes and adding a link between clusters if they were sufficiently close together. In contrast, here we choose regions of the lattice as nodes, and link two nodes if a spin cluster overlaps both node regions and no other node regions, according to the process described in Section 2. As a prominent example, we focus on ground state GHZ clusters of the two-dimensional random transverse-field Ising model (RTIM), but our results apply more generally, as discussed later. In Section 3 we analyze the resulting quantum networks and show that they have a similar complexity to that observed for the classical internet. We discuss the results and conclude by outlining further research directions in Section 4.

2. Quantum network construction

In this work, ground-state spin clusters of the RTIM serve as links for constructing complex quantum networks. As an overview of our construction, network nodes are chosen to be connected regions of lattice sites, with a broad distribution of sizes, for example as shown in Figure 1c. Then, nodes are connected by a quantum link if they both have a site belonging to the same spin cluster, and that cluster has no sites in another node, as shown in Figure 1b.

The two-dimensional RTIM is specified by the Hamiltonian

$$\mathcal{H} = -\sum_{\langle ij \rangle} J_{ij} \sigma_i^x \sigma_j^x - \sum_i h_i \sigma_i^z,$$  \hspace{1cm} (2)

where each $\sigma_i^\alpha$ is the spin-1/2 Pauli matrix in the $\alpha$ direction for a spin at site $i$ of a $L \times L$ square lattice with periodic boundary conditions. The label $\langle ij \rangle$ indicates that the sum is taken over neighboring sites $i$ and $j$ on the lattice, which are coupled by bonds of random strength $J_{ij} \geq 0$, each drawn independently from the uniform distribution on the unit interval. Each site $i$ has a transverse external magnetic field of strength $h_i$. The relevant physics of the RTIM remains unchanged for any non-singular distribution of $h_i$ and $J_{ij}$ as long as at least the $h_i$ fields or the $J_{ij}$ bonds are chosen randomly [36, 37]. Therefore, to simplify the model we consider a ‘fixed-$h$’ model with a uniform magnetic field $h_i = h$ for all sites $i$ [38, 39], unless otherwise stated.

The RTIM is a paradigmatic example of a system which can undergo a quantum phase transition at zero temperature as the quantum control parameter $\theta = \ln h$ is
Complex quantum network models from spin clusters

5

tuned past its critical value \( \theta_c \) [40, 41]. Below \( \theta_c \) the ground state has a macroscopic spin cluster ordered by the couplings \( J_{ij} \), and above \( \theta_c \) the ground state is given by small spin clusters aligned independently. In contrast, at the critical point \( \theta_c = -0.17034(2) \), the spin clusters have a broad size-distribution and are self-similar fractal-like objects [38, 39]. Many properties of the critical RTIM are universal [36, 37], that is, they are independent of the form of the disorder in \( h \) and \( J \), as well as of the type of the 2D lattice.

The ground state of the RTIM can be conveniently determined using the strong disorder renormalization group (SDRG) method [36, 37, 42, 43], which is asymptotically exact in the vicinity of the critical point [44] as demonstrated in both two and higher dimensions [38, 39, 45–52]. We used an efficient SDRG algorithm, which runs in \( O(N \log N) \) time for \( N = L^2 \) sites, to generate instances of RTIM ground state clusters at the critical point [38, 52]. During the SDRG method, the largest local terms in the Hamiltonian are successively eliminated and new Hamiltonians are generated through a perturbation calculation [38]. After decimating all degrees of freedom, the ground state of the RTIM is found to be a collection of independent ferromagnetic clusters of various size, each cluster being in a GHZ state

\[
\frac{1}{\sqrt{2}} \left( |\uparrow \cdots \uparrow\rangle + |\downarrow \cdots \downarrow\rangle \right) \tag{3}
\]

where \( n \) is the number of spins in the cluster. In practice, we considered lattices up to size \( L = 4096 \), with at least 16 instances at each size. An advantage of using the critical point is that it leads to large network size after the network construction is carried out (see Figure 3d), while the SDRG remains asymptotically exact. Note that the ground state of the RTIM factorizes into a collection of independent GHZ clusters even outside the critical point [53], indicating that off-critical RTIMs could also be used.

Let us first consider one of the network nodes, a spatially localized region \( A \) of the RTIM lattice. The entanglement entropy

\[
S = -\text{Tr}(\rho_A \log_2 \rho_A), \tag{4}
\]

which is the von Neumann entropy of the reduced density matrix \( \rho_A \), provides a quantification of the entanglement between \( A \) and the rest of the lattice \( A^c \). In the RTIM, the entanglement entropy is simply the number of clusters with spins in both \( A \) and \( A^c \) [49, 50, 54, 55]. As a special case of the ‘area law’, the entanglement entropy is on average proportional to the surface area (boundary length) of \( A \) [56]. As a consequence, regions with a larger boundary have a larger capacity to establish connections, leading to a proportionally larger expected degree. Therefore, to achieve a heavy-tailed degree distribution for the eventual quantum networks, we aimed to choose node regions with a broad distribution of surface area. As a simple choice, we selected discretized circles of varying sizes in the RTIM lattice as our regions, as shown in Figure 1c. We chose to sample the circles’ radii from a power-law distribution with exponent \( \gamma_{\text{radius}} = 2.67 \).
Complex quantum network models from spin clusters

(Other values of $\gamma_{\text{radius}}$ between 2 and 3 give qualitatively similar results.) A minimum radius of 2 lattice units was used to ensure the disks would consist of at least a few lattice sites. To maximize connectivity, we packed the circles relatively densely on the lattice using the method in Ref. [57]. This method sequentially places circles in an outward-spiralling manner so that a new circle is tangent to one or more of the already placed circles. Note that this method does not attempt to solve the challenging problem of maximizing the packing density, nor is it a uniformly random placement of the circles. In practice, disks were added until a fixed proportion, here chosen to be 0.3, of the lattice sites were covered, as illustrated in Figure 1c.

Now consider two disjoint regions $\mathcal{A}$ and $\mathcal{B}$ serving as network nodes, as well as the rest of the lattice, as shown in Figure 1b. As we partition the system into more than two subsystems, it becomes challenging to quantify quantum entanglement between pairs of subsystems [58], as the entanglement entropy is no longer applicable. As an alternative, one can consider the logarithmic negativity, which is an upper bound for the distillable entanglement, although it is notoriously difficult to compute in practice [59, 60]. In the RTIM, the entanglement negativity is non-zero if and only if $\mathcal{A}$ and $\mathcal{B}$ share a spin cluster that has no sites outside of these two regions [61, 62]. As the most strict construction, we could consider only such clusters as communication channels between the nodes. However, this is overly restrictive in the context of quantum networks, as any cluster that has sites in both regions can be used for communication, as long as the other sites in the cluster remain unchanged. As it is reasonable to assume that spins are only manipulated inside the nodes, we chose to add a quantum link between $\mathcal{A}$ and $\mathcal{B}$ if they both have a site belonging to the same spin cluster, and that cluster has no sites in any other node. Note that in our construction $\mathcal{A}$ and $\mathcal{B}$ are typically adjacent and at least some of the shared clusters are relatively small, meaning that there is a negligible difference between these two alternative cluster selection protocols.

If the resulting network is disconnected (as in Figure 1d), we considered only the largest connected component (LCC) of the network. In other words, each connected component is a separate quantum communication network, and we only consider the largest here.

3. Topological analysis of quantum networks

Visualizations of quantum networks constructed using the method of the previous section (Figure 1e) indicate nontrivial topological features, including highly connected hubs and clustering. This suggests the presence of network complexity, which we verify here numerically. For comparison, we also consider grid-like benchmark networks lacking complexity: quantum networks constructed using the method of Section 2 but with uniformly sized nodes. In this grid-like benchmark, the radius of the nodes was set so that we have the same overall coverage of the RTIM lattice as in our complex quantum networks. The nodes were arranged in a hexagonal packing on the lattice, and as such the resulting networks are expected to approximate a triangular grid. We also compare
Complex quantum network models from spin clusters

Figure 2. Analysis of quantum network topology. a) Degree distribution of a quantum network created with heterogeneously sized (green) or uniformly sized (dark orange) circular nodes on a large RTIM lattice, and the degree distribution of the classical internet at the autonomous systems level on 11/08/1997 (purple) [31]. The dashed line is the expectation for a triangular grid. Inset: The average degree distribution of 16 quantum networks appears to obey a power-law with exponent approximately the same as that of the node size distribution. b) Average shortest path length of networks from a few RTIM lattice sizes. to the topology of the classical internet at the level of autonomous systems from 1997 until 2000 [31]. From 733 available snapshots we selected five representative networks to serve as a basis for comparison, the earliest of which is visualized in Figure 1f.

We first check that the quantum networks have a heavy-tailed degree distribution, a hallmark property of network complexity. As the node size distribution obeys a power-law, the expectation based on the area law is that the degree distribution obeys a power-law with the same exponent, under the assumption that node positions were chosen truly randomly. Indeed, Figure 2a shows a degree distribution of a typical quantum network constructed using the methods of Section 2, with a power-law exponent approximately the same as the one by which the node sizes were chosen. A slight difference in the power-law exponent may be attributed to the non-uniformly random selection of the node regions. The degree distribution is qualitatively similar to that of a representative network of the classical internet at the autonomous systems level, while contrasting with grid-like benchmark networks. The inset in Figure 2a displays an even more clear power-
Complex quantum network models from spin clusters

Another key feature of complex networks is the small-world property. Here, we used the average shortest path length \( \langle d \rangle \) between two nodes as a proxy for the diameter of the quantum networks, shown in Figure 2b for quantum networks from different RTIM system sizes. Though the average path length of the quantum networks is larger than that of the classical internet networks, it is evident that it scales much more slowly than in the grid-like network, which has \( \langle d \rangle \propto \sqrt{N} \). In fact, quantum networks are consistent with a logarithmic relationship \( \langle d \rangle \propto \ln N \), indicating that these networks have the small-world property, although with a somewhat larger diameter than the classical internet.

A closer examination of individual quantum networks reveals that spatially large nodes do not always have a high degree. Depending on the number and size of the surrounding nodes, a large node can often end up with only a few connections, especially if the node is on the periphery of the node packing configuration, or if it is next to other large nodes. We therefore checked for the presence of degree correlations between linked nodes. In Figure 2c the average degree of a node’s nearest neighbors is shown as a function of the node’s own degree. Just like in the classical internet, the negative slope indicates that the quantum networks are disassortative, meaning high degree nodes tend to connect to low degree nodes and vice versa. This contrasts with the grid-like benchmark networks, which exhibit approximately neutral behavior. The observed network disassortativity can be quantified by the degree correlation coefficient \( r \), which is plotted against the network size in Figure 2d. A correlation coefficient \( r = 0 \) means no degree correlations, while negative values indicate disassortativity. Both the quantum networks and the classical internet exhibit disassortativity for all \( N \), but they tend to become less disassortative as \( N \) increases. In contrast, grid-like networks have asymptotically no degree correlations. For small sizes, low degree nodes often appear next to each other in areas dominated by a large cluster in the RTIM, as well as on the periphery of the grid, leading to slightly positive \( r \) values.

Degree correlations capture patterns at the level of pairs of connected nodes, but it is often useful to go one step beyond and check patterns of three nodes. The simplest such measurement is the global clustering coefficient, given by

\[
C \equiv \frac{3 \cdot \text{Number of complete triangles}}{\text{Number of connected triplets of nodes}} = \frac{\sum_{i,j,k} A_{ij} A_{jk} A_{ki}}{\sum_i k_i (k_i - 1)}
\]  

(5)

where \( A \) is the adjacency matrix of the network. The global clustering coefficient of quantum networks of various sizes are shown in Figure 2e. A perfect triangular lattice would achieve \( C = 0.4 \), somewhat above the grid-like benchmark networks that often miss some connections. The clustering coefficient of classical internet networks falls into the range spanned by the heterogeneous and grid-like benchmark networks.

Beyond the global clustering coefficient, we can determine if the network exhibits hierarchical modularity, in which low degree nodes tend to exist in dense communities while high degree nodes connect disparate communities, by examining the relationship
between the local clustering coefficient and node degree. The local clustering coefficient of node $i$ is

$$C_{\text{local},i} = \frac{\sum_{j,k} A_{ij} A_{jk} A_{ki}}{k_i(k_i - 1)}.$$  \hspace{1cm} (6)$$

Hierarchical network structure is indicated by a local clustering coefficient that decays as the node degree increases. As shown in Figure 2f, we indeed observe that $C_{\text{local}}$ decays with $k$ in both the quantum networks and the classical internet network. Further, the local clustering coefficient of the quantum networks obeys the relation $C_{\text{local}} \sim k^{-1}$ well, indicating agreement with the hierarchical network model [63]. Thus the quantum networks share the hierarchical nature of the classical internet, in stark contrast to grid-like networks with no hubs.

4. Discussion and conclusions

In this work, we have introduced a theoretical method to create model quantum communication networks on a lattice of spins using entangled clusters as quantum communication channels. Specifically, we have shown that ground state GHZ clusters of the fixed-$h$ critical RTIM can be used as quantum communication links between local regions of spins, yielding quantum networks with substantial network complexity. As a key implication of the complex topology, the resulting networks are expected to be robust against random node and link failures, while being vulnerable against targeted attacks of the highly connected hubs, similarly to the classical internet and satellite-based quantum communication networks [29].

Our approach can be further generalized, starting with using a non-critical RTIM. In Figure 3a,d we have performed the quantum network construction of Section 2 with the control parameter $\theta$ at various values away from $\theta_c$, and plotted the average size (number of links) of the LCC of the resulting network. For $\theta$ near but not at $\theta_c$, the network construction still produces quantum networks of substantial size, with similar properties and complexity to that found in Section 3. The network size achieves a maximum for $\theta = \theta_c$, although this is a coincidence as criticality is not required in our network construction. What we need is a large number of local clusters, which happens to occur in the vicinity of the critical point for the fixed-$h$ disorder distribution. To show this, in Figure 3b,e we used the box-$h$ RTIM, where the $h_i$ are uniformly distributed in $(0, h]$, with the quantum network construction of Section 2. In this case we observe a slight discrepancy between the critical point and the optimal $\theta$ parameter value. Note that in this system the smaller size of clusters led to much smaller networks on average, but we still expect to see complexity at larger scales.

We may consider further variants of the RTIM, such as the diluted RTIM ($J_{ij} = J \gg h$ with probability $p$, $J_{ij} = 0$ otherwise) [64–67]. This system has connected ground state clusters in the shape of bond percolation clusters, shown in Figure 3d,f, and belongs to a different universality class than the fixed-$h$ and box-$h$ RTIM [53, 55]. Yet, our network construction still leads to large networks of substantial complexity.
More generally, the quantum network construction can be extended to any system with a ground state that factorizes into independent spin clusters. Such systems include the random Potts and clock models [68] as well as the Ashkin-Teller model [69].

As a further extension, spin clusters of different layers could serve both as nodes and links. For example, one layer of the diluted critical RTIM (with percolation clusters) could define the nodes, while another layer could provide the links. As clusters in the critical diluted RTIM have a broad size distribution, much like the circular nodes chosen earlier, they would naturally lead to a broad degree distribution. The volume distribution exponent is given by \( \tau = 1 + D / D_f \), where \( D = 2 \) is the dimension of the lattice and \( D_f = 91 / 48 \) is the fractal dimension of percolation clusters [70].

Our network construction can lead to even more dense and potentially more complex networks by using multiple layers of spin clusters for links. This idea leads to multilayer networks [71], where the union of the links coming from different layers can increase the topological complexity further, no longer resulting in the current, quasi-planar graphs. In both a single-layer and multi-layer construction, we can construct a weighted network,
where the link weight is the multiplicity of the established quantum channels between each node pair. While for a purely topological analysis such weights are irrelevant, they can be of key importance for practical quantum communication protocols [27].

Note that scale-free spatial networks would traditionally require long range connections [27]. As our design includes spatially extended nodes, scale-free quantum networks can be achieved even with only short range connections, like in the optimal off-critical construction in Figure 3f. Our quantum network construction could also generalize to higher dimensions. In 3D, the area law means that the degree distribution is coupled to the distribution of the area of the subsystems instead of their linear extent. Hence the degree distribution is expected to obey a power law with an exponent one larger than the exponent of the linear size distribution. Unlike the networks from the 2D construction, networks from the 3D construction would not be nearly planar, and would likely have higher clustering coefficient. In contrast, the same construction would not work in the 1D RTIM: Since the boundary of a connected region is constant, all connected node regions are expected to have equal average degree. A caveat is that for a 1D RTIM at criticality, there are logarithmic corrections to the area law [72–74]; however, it would be unwieldy to create power law distributions from merely logarithmic corrections.

In conclusion, we have presented a way to create model complex quantum networks on a lattice of spins. As the first application, our work centers around the critical two-dimensional RTIM, but generalizations to other interacting spin systems that admit entangled ground state clusters are apparent. Our model serves as an accessible generative framework for further investigations on network complexity in the emerging quantum internet. Further, our results could motivate experimental work to create a spatially small but many-node complex quantum communication network using a magnetic solid that admits magnetic domains in the form of spin clusters. We believe that in addition to ongoing and future experiments with a few nodes separated at large distances [2, 13–15], we also need small-scale experiments with many nodes to explore the implications of complex network topologies. This is an exciting time to explore the question of quantum network topology, influencing how the quantum internet will be shaped. As of now, it is unclear if the emerging quantum internet will acquire a complex network structure. Even if the quantum internet falls into a novel class of complex networks substantially different from those observed in classical systems, models like the one presented here may be valuable to understand how network properties arise.
