Abstract

There are various environmental factors that need to be considered when assessing the suitability of site for oil palm cultivation some of which are; climate, vegetation, and the soils. Using soil morphology and degree of profile development or the nature of the parent bedrock and the vegetation formed grouped the soil supporting oil palm as generally belonging to five parent materials. The various soil groups includes:- Crystalline metamorphic and Igneous rocks, Shale mixed with sand stone and clay, Coastal plain sand, Coastal alluvium and Fresh water swamp, these groups are presumed to differ on several physiochemical properties and formed the basis on which land is being selected for oil palm cultivation. The classification of soil location in future into any of the five soil types on the basis of the soil characteristics can be facilitated using different approach, but in this study, discriminant analysis will be used to measure the success rate of classifying the soil types by using the physiochemical properties soils in the Raphia growing zone of Nigeria. The research is aimed at applying discriminant analysis thereby satisfying the following objectives: Use discriminant analysis to predict soil group membership in order to correctly classify future unknown observation into any of the five soil groups based on the observed predictors (soil characteristics) in soils supporting Raphia palms of southern Nigeria, Form linear combinations of the discriminating predictor variables that differs significantly in their group means, Identify the soil properties that best discriminates among the soil types. The findings revealed the utility of several multivariate statistical methods for soil research, as well as a better knowledge of soil heterogeneity in Nigeria's oil palm area. This information will be important in measuring soil diversity for crop enhancement and in developing agricultural management strategies, particularly in Nigeria's oil palm area.
Keywords: Discriminant function; soil class; soil characteristics; raphia growing zone; Southern Nigeria.

1 Introduction

The three primary environmental parameters that are usually evaluated when assessing the feasibility of a site for oil palm agriculture are climate, vegetation, and soil [1]. The topography and shape of the soil, as well as the availability of moisture and the physical and chemical qualities of the soil, are all critical. However, in determining the appropriateness of soil for oil palm production and the need for mineral fertilisers, soil chemical features are more essential than soil physical properties. As observed by Paramanthan (2003), soil chemical characteristics are more easily changed compared to soil physical properties. Some very important chemical properties useful to oil palm are: Organic matter, Nitrogen (N) content, Soil Phosphorus (P), Effective Caution Exchange Capacity (ECEC), Potassium (K), Calcium (Ca), Magnesium (Mg), Soil pH and micronutrient toxicity. The knowledge of these soil properties and their response to management practices is an essential requirement by any land users or oil palm growers.

Nigeria's oil palm belt covers a large area of land, and each soil site has its own unique qualities. The degrees and patterns of soil diversity in a site or location with similar soil qualities are known. When soil series are reasonably homogeneous, it allows for some special management decisions. For example, an experiment can be carried out, and the knowledge obtained is helpful not only for the specific place, but also for other locations within the groups or cluster. In comparison to a site-by-site investigation, a group-specific investigation will aid in the development of management approaches and recommendations that will result in a large reduction in the cost of doing research and deliver maximum advantages to other stakeholders. The natural system method to soil classification has become one of the most popular. This approach involves grouping soils based on their inherent qualities (soil morphology), and includes systems like USDA soil taxonomy, FAO and French systems, Kang, and others [2]. But the USDA and the FAO systems have received worldwide attention and are the most used in Nigeria [3]. In recent years, development and application of quantitative techniques have generated considerable interest in numerical techniques as a complementary tool to better understanding of ecological or environmental relationships. This technique has been applied to a wide variety of research problems especially in the classification of field crop genotype. Omokhafe [4] has reported on the use of clustering technique in tree crops. However, despite the wide use of numerical methods in classification in these areas, hierarchical cluster analysis has received little attention in soil classification research.

Discriminant analysis is a multivariate statistical approach that uses a set of predictors to determine group membership (variables) [5]. This statistical method appears to have important applications for soil classification, but has received little attention from pedologist [6] described important justifications for the application of multivariate statistical method to the study of soil science. These methods interrelated variables which define soils. Multivariate analysis allows an objective, unbiased extermination of the variables, thus ensuring that a priori perceptions do not lead to incomplete or faulty conclusions. Finally, the knowledge of statistical methods required by proper application of multivariate analysis should result in a precise and repeatable conclusion not possible with non-numeric methods (Norris, 1970).

Among the previous applications of discriminant analysis to soil science have been the identification of representative general classes of soil within an extensive geophysical province (Webster and Burrough [7]) and classification of soil developmental sequences in sand dunes [8]. Edmands and Lentner [9] reported that discriminant analysis was better to predict soil response classes than soil Taxonomy. Lentz and Simonsen [10] used discriminant analysis to classify soils associated with sagebrush communities. Other soil qualities than those utilised in soil taxonomy were shown to be key discriminators between soil classes in the study. We are not aware of any attempts to investigate the link between soil landforms using a large data set and discriminant analysis (Land types).

2 Materials and Methods

The data used for the study are from Chemistry Division, Nigerian Institute for oil Palm Research (NIFOR). The soil samples were taken from 57 locations belonging to five soil types in the southern part of Nigeria, an area believed to be suitable for Raphia palm cultivation. For each of the 57 samples the physiochemical properties
were obtained from five soil types. Five soil types and its physiochemical properties are listed in the Table 2.1 and 2.2 respectively.

Given a set of W independent variables \(X_1, X_2, \ldots, X_W\) (Soil characteristics in this case), Multiple Discriminant Analysis (MDA) attempts to find the linear combination (Discriminant Function) of these variables that best separate the groups of cases \(Z_1, Z_2, \ldots, Z_5\) (Soil types in this case). The functions are generated from a sample of cases for which group membership is known; the functions can then be applied to new cases with measurements for the predictors variables, but unknown group membership.

In general form, the discriminant function is expresses as:

\[
Z = a + W_1X_1 + W_2X_2 + \cdots + W_WX_W
\]

Where
- \(Z\) = Discriminant Score, \(X_k\) = an independent variable or predictor variables.
- \(a\) = Discriminant Constant, \(W_k\) = Discriminant weight or Coefficients.

### Table 2.1. Parent material (soil type) and group code

| Group code | Soil types                      |
|------------|---------------------------------|
| 1          | Crystalline Metamorphic and Igneous rocks |
| 2          | Share Mixed with Sandstone      |
| 3          | Coastal Plain Sand              |
| 4          | Coastal Alluvium                |
| 5          | Fresh Water Swamps              |

### Table 2.2. Soil-site characteristics measured

| Variable Code | Code for soil properties | Soil properties |
|---------------|--------------------------|-----------------|
| \(X_1\)       | Ph                       | Soil pH         |
| \(X_2\)       | Orgm                     | Organic matter  |
| \(X_3\)       | N                        | Nitrogen        |
| \(X_4\)       | P                        | Phosphorus      |
| \(X_5\)       | K                        | Potassium       |
| \(X_6\)       | Ca                       | Calcium         |
| \(X_7\)       | Mg                       | Magnesium       |
| \(X_8\)       | S                        | Sulphur         |
| \(X_9\)       | Fe                       | Iron            |
| \(X_{10}\)    | Mn                       | Manganese       |
| \(X_{11}\)    | Cu                       | Copper          |
| \(X_{12}\)    | Zn                       | Zinc            |
| \(X_{13}\)    | B                        | Boron           |

The approach selects a first function that will separate the groups as much as possible, followed by a second function that is both uncorrelated with the first and provides as much separation as possible. The procedure continues adding functions in this way until reaching the maximum number of functions as determined by the number of predictors and groups in the dependant variables. In two group discriminant function, there is only one discriminant function. But for higher order discriminant function, the number of functions each with is own cut-off point value is the lesser of \(g-1\), where \(g\) is the number of categories in the grouping variables. Each discriminant function is orthogonal to the other.

The discriminant ability of the functions will be determined by the following statistic, The Eigen-value, Canonical correlation and The Wilks’ Lambda.

i. Eigen-value \((\lambda)\) also called the characteristics root indicates the relative discriminating power of the discriminant functions. There is one Eigen value for each discriminant function. With more than one
function, the first function will be the largest and the most important, the second next most importance in explanatory power and so on. This can be simply defined as:

$$\lambda = \frac{BSS}{WSS} \left[ \sum (Z_j - \bar{Z})^2 / \Sigma(Z_{ij} - \bar{Z}_j)^2 \right]$$

Where BSS is between group variance and WSS is within group variance:

If $\lambda = 0$, the model has no discriminant power. The larger the value of $\lambda$, the greater the discriminant power.

ii. The Conical Correlation ($\eta$) eta is a measure of the association between groups formed by the dependent variable and the given discriminant function and this can be defined as:

$$\eta = \sqrt{\frac{\lambda}{1 + \lambda}} = \sqrt{\frac{BSS + TSS}{TSS}}$$

Where BSS is between group variance and TSS is total variance.

$\eta$ = The correlation of the predictor(s) with the discriminant scores produced by the model (measure the association between discriminant scores and the groups).

$\eta^2 =$ Coefficients of determination.

$1 - \eta^2 = $ Coefficient of non-determination.

when the canonical correlation is large (near 1), it indicate that there is high correlation between the discriminant functions and the groups (i.e the function discriminates well among the groups. But when the correlation is zero. It means there is no correlation between the groups and the functions.

iii. The Wilks Lambda used to test the significant of the discriminant function as a whole and this can be defined as:

$$\Lambda = (1 - \eta^2) = \frac{1}{\lambda + 1} = \frac{WSS}{TSS}$$

Where WSS is within variance sum of square and TSS is the total sum of square.

A significant lambda, means one can reject the null hypothesis, which says that the two or more groups have the same mean discriminant function score. The chi-square ($X^2$) is then used to tests the significance of the difference in the mean discriminant score between groups and is defines as:

$$X^2 = -[(n - 1) - 0.5(m + k + 1)]ln \Lambda$$

$k - 1 =$ degree of freedom (df) of a given function. It is based on the number of groups present in the categorical variables and the number of continuous discriminant variables.

The chi-square statistic is compared to a chi-square distribution with the degree of freedom stated here. However, the p-value associated with the chi-square statistic is given. For a given alpha level say 0.05, if the p-value is less than alpha, the null hypothesis that a given function canonical correlation and all smaller canonical correlations are equal to zero is rejected. If not, then we fail to reject the null hypothesis.

In testing the classification performances of the discriminant function, we used the overall hit ratio which is the same thing as percentage of the original group cases correctly classified. Three benchmarks are used. The Maximum Chance Criterion (MCC), Proportional Chance Criterion and Press’s Q statistic are used to test the significance of the Hit ratio. If the hit ratio exceed the groups maximum and the proportional chance value, the model is said to be significant better than chance. This statistic can be defined as follows:

- Maximum Chance Criterion

$$\text{MCC} = \left( \frac{N_i}{N_j} \right) \times 100$$

Where

$N_i =$number of subjects in the largest group
$N_S = \text{total number of subjects in the combined}$

- **Proportional Chance Criterion**

$$C_{pro} = \sum P_j^2$$  

2.6

Where

$P_j = \text{Proportional of subjects in each group.}$

- **Press Q statistic**

$$Q = \frac{[N - (n)(g)]^2}{2} / [N - (g - 1)]$$  

2.7

$N = \text{total number of subjects}$

$n = \text{number of cases correctly classified}$

$g = \text{number of groups}$

$Q \sim \chi^2_{g-1}$

The value of $Q$ is compared to the chi-square distribution at $g-1$ degree of freedom since $Q$ is approximately the chi-square value and if $Q < \chi^2_{g-1}$, reject the null hypothesis that the model hit ratio is not significantly better than chance, otherwise accept.

In constructing the classification matrix, the cutting score was used. For equal groups, it is half way between the two groups centroid. This is defined as:

$$Z_{cs} = N_AZ_B + N_BZ_A/N_A + N_B$$  

2.8

Where

$Z_{cs} = \text{Optimum cutting score between group A and B}$

$N_A = \text{Number of observation in group A}$

$N_B = \text{Number of observation in group B}$

$Z_A = \text{Centroid for group A}$

$Z_B = \text{Centroid for group B}$

$$Z_{cs} = Z_A + Z_B/2$$  

2.9

Where

$Z_{cs} = \text{Optimal cutting score for equal size}$

$Z_A = \text{Centroid for group A}$

$Z_B = \text{Centroid for group B}$

In order to determine the significant of the predictors, the differences among the groups are tested. In this case we will test the following hypothesis.

$$H_0: \mu_1 = \mu_2 = \mu_3 = \mu_4 = \mu_5;$$

$$H_1: \mu_1 = \mu_2 = \mu_3 = \mu_4 = \mu_5.$$  

Where

$\mu_1 = \mu_2 = \mu_3 = \mu_4 = \mu_5$ are the population means of group 1,2,3,4, and 5 respectively.

The above hypothesis can be tested using the wilk’s lambda test statistic which may be defined as:

$$\lambda = WSS/TSS = \frac{\sum(Z_j - \bar{Z})^2}{\sum(Z_{ij} - \bar{Z_j})^2}$$  

2.10
Wilks’ lambda ranges from 0 to 1. A small value indicates strong group differences. Values close to 1 indicates no group differences. Also the smaller the lambda for an independent variable, the more the variable contributes to the discriminant function.

The F-test of Wilks’ lambda shows which variables contributions are significant. The F-test can be defined as:

\[ F = \frac{1 - \lambda_k - 1/\lambda_k}{1/\lambda_k / [N - g - 1/1 - 1]} \]  

3.11

Where,

\( N \) = total sample size,
\( G \) = number of defended variables (group),
\( \text{d.f} \) (\( N - g - 1 \)) and (\( g - 1 \))

If the significant value is small (< 0.05), this indicates that the variable contributes to group differences.

### 3 Results and Discussion

The result obtained from the analysis for the four discriminant functions is shown in Table 3.1 below. The coefficients of the discriminant functions provide an index of the importance of each predictor while the sign indicates the direction of the relationship in the first function which was significant at (p< 0.05), N was the strongest predictor while pH was next importance as predictor. Both predictors have positive relationship with the soil types. For the remaining three functions, K, N and pH are strong predictors for the second function while K and N were the only strong predictors for the third and fourth functions respectively. The implication of this is that these variable (N, pH, K) with large coefficients stand out as those that strongly predict allocation to the soil types or groups and that the score of the other soil characteristics were less successful predictors.

Table 3.2 shows the following statistic, the Eigen values, Canonical correlation, Wilks’ lambda, its Chi-square and the associated p-value (sig). These statistics help to describe the discriminating abilities of the function. Four functions (Table 3.1) were estimated, and only one function with the higher Eigen-value (1.315), which explain the variation of the soil group types by 55.6\% (Table 3.2) was significant and feasible for further used. The estimated Canonical correlation to measure the association between the groups and the discriminant score is 0.754, this shows that the model discriminates well among the five groups. The wilks’ lambda is 0.178, which implies that there is significant variation in the soil types grouped in the discriminant model. Approximately, 55.6\% of the variation is explained by the differences between the groups (1,2,3,4, and 5). The Chi-square statistic have the value (82.503) and significant at (p< 0.05) indicating that, there is significant difference between group centroids. From the wilks’ lambda and Chi-square results, we reject the null hypothesis of the equal mean between the groups. The estimated Press’s Q statistic is 8.96 and this greater than chance value, implying higher power of the discriminant model is established for grouping the soil types in the study area, hence more credit to the model for further analysis.

### Table 3.1. The linear discriminant function coefficients for the soil groups

| Variables | \( Z_1 \) | \( Z_2 \) | \( Z_3 \) | \( Z_4 \) |
|-----------|-----------|-----------|-----------|-----------|
| Constant  | -4.403    | 4.949     | -5.567    | -1.930    |

| Zn        | 0.005     | 0.049     | 0.035     | -0.003    |
| B         | 0.625     | 0.090     | 1.084     | 0.689     |
Table 3.2. Test of significant for discriminant function

| Function | Eigen-values | Percentage of Variance | Canonical Correlation | Wilks’ Lambda | Chi-square | Significant value |
|----------|--------------|------------------------|-----------------------|---------------|------------|-------------------|
| 1        | 1.315        | 55.6                   | 0.754                 | 0.178         | 82.503     | 0.004*            |
| 2        | 0.491        | 20.7                   | 0.574                 | 0.415         | 42.211     | 0.221             |
| 3        | 0.433        | 18.3                   | 0.550                 | 0.619         | 23.039     | 0.400             |
| 4        | 0.128        | 5.4                    | 0.336                 | 0.887         | 5.767      | 0.834             |

Table 3.2 shows a comparison of the actual groupings of the five soil types to the predicted groupings generated by the discriminant functions. In the group 1 and 5, 75% of the cases were correctly classified, indicating a very good performance of the discriminant functions, while groups 2 and 4 predictions were barely less than 60%. The percentage of the cases correctly classified (hit ratio) was 67.7% while about 33% of the cases were classified wrongly. This result compare favorable with 67% recorded by (Fincher and Marie-Louise Smith in [11] and 72% by Stancy cambell, [12] when discriminant predictive method is used for soil group membership prediction. But when compare with the results from other areas of the applications such as education and social sciences, the result could not be said to be remarkable. The reason for this could be due to insufficient variations in soil characteristics between groups to distinguish one source from the other. Another problem might be the number of groups. As (Stancy, 2004) suggested, the larger the number of groups, the chance of misclassification.

The predictive accuracy of the model was measure by the above values (Table 3.4). The overall hit ratio was 67.7% and this exceeded both maximum chance and proportional chance values of 27.59 and 21.22 percent respectively. The Press’s Q statistic of 347.57 was greater than the tabulated value (11.1), indicating that the prediction accuracy is greater than that expected by chance.

Table 3.3. Classification performance of the estimated discriminant function

| Actual Group | Number of Cases | Predicted Group | Memberships |
|--------------|-----------------|-----------------|-------------|
|              |                 | 1(75%)          | 2(12.5%)    | 0(0%)       | 0(0%)       | 2(12.5%)       |
| 1            | 16              |                 |             |             |             |
| 2            | 12              | 1(8.3%)         | 7(58.3%)    | 2(16.7%)    | 0(0%)       | 2(16.7%)       |
| 3            | 13              | 0(0%)           | 1(7.7%)     | 9(64.2%)    | 1(7.7%)     | 2(15.4%)       |
| 4            | 9               | 1(11.1%)        | 1(11.1%)    | 1(11.1%)    | 5(56.8%)    | 1(11.1%)       |
| 5            | 8               | 0(0%)           | 0(0%)       | 2(25.0%)    | 0(0%)       | 6(75.0%)       |

67.7% of the cases was correctly classified
32.3% of the cases not correctly classified

Table 3.4. Comparison of goodness of results

| Measure           | Value   |
|-------------------|---------|
| Maximum Chance    | 27.59   |
| Proportional Chance| 21.22   |
| Hit Ratio         | 67.7    |
| Press’ Q calculated value | 347.57 |
| Press’ Q table value | 11.1   |

Table 3.5 shown below contains Wilks’ lambda, the F statistics and its significance level. From the table, seven (7) predictor variables (pH, P, K, Ca, Mg, Mn and Cu) were significant of the thirteen (13) variables used in the model. The result shown that Mg is the best in discriminant among the groups, and closely followed by pH, P, Ca, Mn, Cu and finally K. The implication is that soil types are determined by these seven variables, and the inter group difference among the remaining six variables are not wide enough in discriminating among the groups. This means that the Orgm, N, S, Fe, Zn and B within the groups in the study areas are almost the same.
Table 3.5. Characteristics of soil locations that best discriminate among the five soil parents material

| Variables | Group 1 Mean | Group 2 Mean | Group 3 Mean | Group 4 Mean | Group 5 Mean | Wilks’ Lambda | F-value | P-value |
|-----------|-------------|-------------|-------------|-------------|-------------|---------------|---------|---------|

*Significant (p < 0.05)

From the analysis, the following findings and conclusion were drawn. Discriminant analysis completely reduced thirteen (13) physical characteristics used in the study to seven (7) component indicating that fewer variables such as Mg, P, Cu, pH, Ca, Mn, and K are sufficient to explain the nutrient requirement of the oil palm within the belt. This shown that with fewer soil properties, we can sufficiently describe the nutrient required and information about the relative importance of each of the soil properties in characterizing the soil. The cluster analysis completely grouped the 57 agricultural fields into five groups of similar pattern indicating that the diversity of soil within the belt can be grouped into five according to the soil properties.

Four Discriminant functions were extracted in the analysis but only the first function was significant, of the variance explained by the four functions, 55.6% was explained by the first function while 20.7%, 18.3% and 5.4% were explained by the second, third, and fourth functions respectively. The canonical correlation indicate a very strong correlation between the discriminant score and the groups using the first function while the correlation between the other three functions were weak. The wilks’ lambda for the first function was significant while the overall hit ratio of the model is 67.7% and this was shown to be significantly better than chance. The test for the equality of group means shown that seven out of the thirteen predictor variables were significant, indicating that these variables will be useful in classifying new observations drawn from the same populations as the original sample groups.

4 Conclusion

Finally, the result has shown that the discriminant analysis is a fairly good method for predicting new cases into any of the five soil types in the Raphia growing zone of southern Nigeria and that Mg, P, Cu, pH, Ca, Mn, and K were identified as the soil properties that best discriminates among the soil types in the zone studied.

Acknowledgements

My deepest gratitude goes to Almighty Allah for His mercies and His grace, and our beloved prophet Muhammed (S.A.W). I personally wish to appreciate my mother Mrs. Musiliat Igbalaye for her love, care, and prayers. And my dear father Alhaji Rasheed Igbalaye for his wonderful words of encouragement and support.

Special thank to my mentor Mr. A. Austin Edokpayi of Nigerian Institute for Oil Palm Research (NIFOR), for his support and ability to supervise my work.

My sincere appreciation goes to my lovely wife Mrs. Risqut Saheed for her understanding and support towards the success of this work, and finally I will never forget to mention the name of my children Amirah Gold Igbalaye and Furqan Akinkunmi Igbalaye.
A million thanks to my Boss Mr. N’Dekre Josheph Tetchi of XC International Excellence University, Abidjan. And finally, my appreciation goes to Mr. Atoyebi Samuel.
